About the Editor

Mark Garrett holds a Ph.D. in urban planning from the University of California, Los Angeles (UCLA) Luskin School of Public Affairs and a J.D. from the UCLA School of Law. For a number of years he was a practicing attorney in California specializing in land use, transportation, and environmental issues. He is currently serving as a member of the research faculty in the Lewis Center for Regional Policy Studies at UCLA and also teaches courses in the Department of Urban Planning. Garrett is the co-author with Martin Wachs of *Transportation Planning on Trial: The Clean Air Act and Travel Forecasting*, and has contributed to articles in the *UCLA Journal of Environmental Law and Policy*, the UCLA journal

Critical Planning, the *Berkeley Planning Journal*, the *Transportation Research Record*, and the *Journal of the American Planning Association*.

Garrett has been an adjunct professor in the Saint Louis University (SLU) School of Law and a faculty member in the Department of Policy Studies in SLU's College of Education and Public Policy. He has also taught at the Ohio State University, the University of Michigan, the University of Illinois, and Virginia Commonwealth University.

His current research focuses on sustainability and legal and social equity aspects of urban land use and transportation planning. He presently resides in Los Angeles, California.

Introduction

We all rely on transportation. Whether it is flying to some faraway destination, taking a cruise, driving to work, bicycling through a park, or just walking around the block, we depend on a system of airports, harbors, railroads, highways, streets, and sidewalks to help get us where we need or want to go. Even without leaving our homes, we still depend on those who use transportation systems to deliver food to the grocery stores, consumer goods to local stores and shopping malls, and packages and mail to our front door. For the most part, all these systems, and more, require planning, construction, and maintenance, sometimes by private individuals and organizations but more often by various agents of government, whether at the local, state, national, or in some cases, international scale. None of us could survive unless legions of planners, policy makers, engineers, construction workers, air traffic controllers, drivers, ticket agents, road crews, police officers, school crossing guards, and many others worked tirelessly to keep the transportation network running smoothly and safely.

In addition to those who provide us with transportation systems, there are also many who study transportation systems and those who use them. They ask questions such as these: Where do people go? How do they get there? What types, or modes, of travel do they use? When are they most likely to travel? And perhaps most importantly,

why do they travel? All these questions are important to improving the service that transportation systems provide, but there is another set of questions that also concern those who deal with the policy aspects of transportation—namely, how do transportation systems affect our daily lives, and how will they shape our future?

Transportation consumes land and nonrenewable resources, generates noise, air pollution, and waste material, and results in the injury or death of thousands of individuals annually involved in transportation-related accidents. Increasingly in the industrialized world, people live far from their place of work or where they can shop. Millions of people spend a good part of their days in transit—some stuck for hours in traffic congestion. For others, their lack of access to either private or public transportation limits their mobility and greatly reduces their opportunity to lead useful and productive lives. All these issues, and others at varying times and in varying degrees, concern social scientists and policy makers involved in transportation. Accordingly, this volume brings together the latest research and thinking about transportation planning and policy by some of the leading figures in the field.

A Brief History of Transportation Policy

People have always moved about from place to place, often by following animal tracks that over

time become established roads. Mariners have long followed favorable winds and currents, passing their knowledge down to others. But, even conscious efforts to design and build transportation systems have a long history. The Phoenicians, Egyptians, Greeks, and Chinese all built harbors and canals to support long-distance trade. The Romans were renowned for constructing paved roads stretching across continents, as did the pre-conquest Peruvians.

The 19th Century. In North America, the desire of colonists to exploit their vast hinterlands led to the creation of the first National Road, an inconsistently built and maintained macadam pathway begun in 1811 at Cumberland, Maryland, and ultimately stretching through Pennsylvania, Ohio, and Indiana to Illinois—later U.S. Highway 40 and today more or less the route of Interstate 70—carrying settlers to Pittsburgh, Wheeling, Columbus, Indianapolis, and Terre Haute. At the beginning of the Industrial Age, steamboats carried passengers and freight deep into the new western territories after Fulton and Livingston's successful demonstration in 1807.

Forward-thinking entrepreneurs also developed canals to take goods to market, the Erie Canal completed in 1825 at a cost of \$7 million connecting Albany and Buffalo, New York, being perhaps the most famous—and linking the growing port of New York City to the Great Lakes and the vast resources of the northwest—but scores of others, large and small, were constructed in Virginia, Ohio, Indiana, and elsewhere. They were, however, quickly superseded by the newest marvel, the steam locomotives, whose spreading tracks began knitting together cities and regions into an ever-expanding economic network.

The meeting of the Union Pacific and Central Pacific Railroads at Promontory Summit, Utah, in 1869 completed the route selected by President Abraham Lincoln from Omaha, Nebraska, to Sacramento, California, forever joining the markets of the east to the west coast. Bridges of wood, iron, and later steel (the first use being the 1874 Eads Bridge in Saint Louis) spanning great rivers soon replaced ferry boats, making seamless travel possible across the nation. In the burgeoning industrial cities, omnibuses and steel-tracked horsecars carried workers from growing

residential enclaves to their work in factories and towering office buildings in the emerging central business districts. By the height of the Industrial Age, the perfection of a practical electric motor and transmission lines (first put in service in Richmond, Virginia, in 1888) heralded the beginning of the streetcar era; trolleys and interurbans fanned out over the countryside, vastly expanding the size and shape of the modern city and setting the stage for its now characteristic pattern of sprawl.

Often this took place with little or no government involvement beyond granting local franchises to transportation operators for ferries, streetcars, bridges, or toll roads (the Pennsylvania Turnpike began as a private toll road from Philadelphia to Lancaster in 1795), though other transportation systems like the Transcontinental Railroad mentioned previously required congressional funding. State and municipal regulation was likewise limited at first; some safety measures were adopted, and operators were typically charged with maintaining roadways under their control, but government was largely content to allow private enterprise to supply whatever the public desired in the way of transportation services.

The 20th Century. All that began to change at the dawn of the 20th century. Even before the newfangled automobile came into widespread use, bicycle enthusiasts and rural farmers began a campaign to improve the deplorable condition of the vast majority of the country's highways and byways. (Europe already had a history of national support for road construction.) This Good Roads Movement put pressure on states and the federal government to grade and pave dirt roads, connect rural areas to cities, and establish a national network of interstate highways. Congress passed the first Federal Aid Road Act in 1916, which provided funding for rural post roads, followed by the 1921 Federal Highway Act, which expanded funding for federal-aid highways to be built by publically funded state highway departments once approved by the new federal Bureau of Public Roads.

By 1923, the bureau had designated the complete federal-aid system, connecting every city over 50,000 in population, much of which would be completed by the late 1930s. Federal funds could

not at the time be used on urban roadways, and so, the program was still a decidedly rural one, though in urban areas, traffic congestion was becoming an increasing concern. The first federal gasoline tax, a mere 1 cent per gallon, was passed in 1932 as a temporary revenue measure but proved so lucrative that it was easily renewed in 1933 under the Roosevelt administration, which also backed legislation to fund urban road projects. The Hayden-Cartwright Act of 1934 ended the prohibition on using federal aid funds in urban areas and designated urban secondary roads as part of the federal aid highway system, thereby providing routine federal transportation aid to urban areas.

In 1939, General Motors Corporation sponsored a hugely popular exhibit called Futurama at the New York World's Fair, extolling the benefits of a safe, modern, high-speed national highway system and documenting the company's efforts in a promotional film titled *To New Horizons*, designed to build even more support for the project among the public and important policy makers. Perhaps not coincidentally, also in 1939, President Roosevelt endorsed the federal Bureau of Public Road's master plan for a national system of limited-access roadways covering 27,600 miles and extending the routes directly into urban areas. This road network was to be accessed only at interchanges, grade separated from cross traffic and trains, and free of tolls.

The new superhighways were to penetrate to the very heart of every major U.S. city, and larger metropolitan areas would have both inner and outer beltways. While widely popular, plans for the system were shelved while the nation struggled through the Great Depression and World War II. By 1944, interest in public highway projects as a way to ease the transition to a peacetime economy led to enactment of the Federal Aid Highway Act of 1944, which designated up to 40,000 miles of high-speed, limited-access freeways. The official routes, published in 1947, included 3,900 miles of highway extensions within urban areas and another 2,200 miles, also to be built within urban areas, seen as important to gaining urban political support for the highway program.

In the years following World War II, these efforts bore fruit in the form of the 1956 Federal Aid Highway Act, which financed the now 41,000-mile National System of Interstate and

Defense Highways. Signed into law by President Eisenhower, who as a young army officer had taken part in a two-month cross-country military convoy intended to highlight the poor conditions of the nation's roads, and who as World War II general saw firsthand the military and civilian potential of the German *Autobahn*, the legislation marked the beginning of the American freeway-building era. Congress increased the gas tax to 3 cents a gallon, placing these and other excise revenues in a Highway Trust Fund to be used exclusively for highway projects. Many of those inner-city freeways would become part of local urban renewal projects, frequently targeting poor and minority neighborhoods for removal and thus seriously tarnishing the freeway program's reputation. For returning veterans and other white citizens who qualified for low-interest home loans, though, the 1956 act and subsequent federal highway legislation literally paved the way to the suburbs and the American Dream.

The American obsession with road building did not extend to providing urban mass transit, which unlike in Europe and elsewhere, was historically not seen as a government concern. Transit companies, then mostly privately owned and struggling financially after a brief surge in popularity during World War II, soon succumbed to the increasingly suburban and automobile-oriented lifestyle. Many bankrupt systems were eventually acquired by local governments, often with federal funds, as Congress began to haltingly address the growing transportation problems of urban areas. The U.S. government in the 1960s began requiring continuing and comprehensive transportation plans be developed as a coordinated part of an overall regional planning process designed to rehabilitate urban areas and used its discretionary power over federal funds to promote that goal by conditioning project approvals on metropolitan-wide plans developed through what came to be known as the 3C planning process. Metropolitan Planning Organizations (MPOs) became the primary bodies responsible for highway and public transit planning in urban areas.

The Urban Mass Transportation Act of 1964 marked the first legislation to provide direct federal assistance for transit capital projects, authorizing discretionary grants for up to two-thirds of the net project costs of constructing or acquiring

mass transportation facilities and equipment in areas that had completed their regional plans. The 1966 amendments to the act provided federal matching funds for planning, engineering, and design of urban mass transportation projects and acquisition of remaining private transit operations. By the early 1970s, with most private transit properties having been purchased and bus fleets modernized and upgraded, a shift occurred in federal policy toward greater emphasis on expanding mass transit, particularly rail construction, in response to environmental and other social concerns and as a tool to counteract urban sprawl.

The Federal Aid Highway Act of 1973 introduced new flexibility in transit funding, significantly broadening the scope of MPO's responsibility to balance highway and transit spending. Since the mid-1970s, congressional transportation legislation has reflected a major shift in priorities toward addressing environmental concerns, beginning with the 1977 amendments to the Clean Air Act, which mandated greater coordination between transportation and environmental planning. The 1970s also ushered in an era of deregulation, particularly in the airline and passenger and freight railroad industries, generating greater competition but also raising concerns over the availability and quality of service, particularly in smaller market areas.

The 1990 Clean Air Act Amendments significantly expanded efforts to curb transportation-related emissions by reducing the growth in automobile travel, in effect making pollution reduction the driving force behind transportation planning. This legislation was accompanied by the landmark Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991, intended to develop an economically efficient and environmentally sound national intermodal transportation system. ISTEA reinforced the planning requirements of the Clean Air Act by requiring a statewide transportation planning process that considers economic, energy, environmental, and social effects of highway and transit programs and projects. The acts require new, detailed, accurate analyses of the potential impacts of transportation improvements on congestion, travel, and land use but, most importantly, seek to coordinate planning over air, land, or sea, and for all modes of travel, whether

by planes, trains, automobiles, transit, bicycles, or even walking.

Current Issues

What does the future hold for transportation policy and research? Environmental issues will undoubtedly continue to be at the forefront as the world grapples with climate change: How do we reduce the use of polluting fossil fuels, particularly given increasing demand for automobiles brought on by the emerging economic wealth in places like China. And, if we do begin phasing out gasoline engines, how do we build the infrastructure—a network of charging stations like those now available for petroleum-based fuel—to make the transition to electric-powered vehicles possible? Will any success in reducing pollution even be enough, or must we begin to fundamentally rethink our reliance on private vehicles, however powered, or face more unproductive time spend in traffic jams?

Another continuing area of concern is safety and security, such as how to reduce the number and severity of automobile accidents, how to make car and plane crashes more survivable, and how to reduce the risks from terrorism, especially given the increasing reliance on electronic transportation monitoring and guidance systems that could be vulnerable to cyber attacks?

Future transportation planning and policy will undoubtedly continue to be tied to our use of land. Can we encourage new urban forms that fight sprawl and make it easier to use public transit? New movements, such as “complete streets,” challenge us to rethink our transportation systems as an integral component of the public space, providing for walking, bicycling, autos, and public transit in ways that enhance the urban experience rather than erecting more barriers to social and personal interaction. On a larger scale, as globalization takes greater hold, and more and more raw materials and finished products are being shipped around the world, what will the next generation of airports, shipping terminals, and distribution routes look like? Can transportation systems adapt to the changing patterns of urbanization and vice versa?

Other continuing concerns reflect how to pay for our existing transportation systems, many of which are in great need of repair or upgrades to meet growing demand. As we make substantial

investments in our transportation infrastructure, the question of the equitable distribution of benefits and costs will become even more critical. Should transportation be privatized, or should the public sector remain primarily responsible? Which modes should be subsidized? Who should pay: users, the general public, or some combination?

How will the information revolution affect the need to travel and the ways we travel? Can it be used to connect travelers with useful, real-time information or even be used to control the movements of both public and private vehicles? What impact will the growth of social media have on transportation? Perhaps the information age will severely reduce our need to travel as more and more of our daily needs can be met electronically. But if that is to be, what alternative investments should we be making? In some sense, the changes taking place are so new that it is hard to even imagine what questions to ask. Is it too early to start thinking about building skyports to serve low-orbit commercial space flights?

There are also institutional challenges ahead. Are there better ways to predict and plan for travel demand, both personal and commercial? Who should decide what to do with the

increasingly detailed personal travel information collected by mobile telecommunications devices? What role should the public play in deciding the future of the next generation of transportation systems? Many of the great planning disasters have revolved around transportation projects that failed to consider their social and environmental impacts and relied too heavily on technical expertise without consulting with, much less collaborating with, those affected by official decision making. Can transportation policy and planning be more democratic? Can they become more responsive to the needs of the poor and those with limited mobility? And, if so, has the era of the mega transportation projects in the United States drawn to a close?

These and many other critical issues facing the United States and the rest of the world are addressed, if not completely answered, among the many entries that follow. I would like to thank the many generous contributors who gave their valuable time and considerable knowledge in helping realize this project.

Mark Garrett
Editor

Chronology

ca. 4000 B.C.E.: Roads in the Mesopotamian city of Ur are paved with stone, making them among the first manufactured roads in the world.

ca. 3300 B.C.E.: Log “corduroy” roads are built across marsh ground near Glastonbury, England, by laying individual logs perpendicular to the movement of traffic.

ca. 3000 B.C.E.: Roads paved with brick are constructed in India.

ca. 500 B.C.E.: The Persian emperor Darius I builds a great network of roads, including the royal road from Susa to Sardis.

312 B.C.E.: Construction begins on the Roman road known as the *Via Appia* or Appian Way, running from Rome to Brindisi in southwestern Italy.

ca. 47 C.E.: Construction by Roman legions begins on the Fosse Way in Britain, a road linking Somerset with Lincoln.

ca. 610: In China, construction begins of the Grand Canal linking the Yangtze and Yellow Rivers.

1271: The Venetian merchant Marco Polo sets off for Asia; he returns almost 25 years later, and

his accounts of Eastern lands make him famous, although some there was dispute whether he had actually visited some of the places he described.

1391: In Germany, construction begins on a canal to link the Baltic and North Seas.

ca. 1500: In Milan, the first modern canal lock gates are installed.

ca. 1500: In South America, the Inca Empire includes a vast network of roads designed for caravans of llamas.

1610: In Britain, stagecoach service begins operation between Edinburgh and Leith; it is the first such service to use regularly spaced posthouses to change horses.

1630: The British entrepreneur Huntington Beaumont builds plank roads to accommodate heavy, coal-laden carts drawn by horses.

1660s: In Austria, an iron-spring suspension system for coaches is developed that greatly improves the comfort of the ride and helps popularize coach travel, as opposed to riding horseback.

1681: In France, the Briare Canal is completed, joining the Seine and Loire Rivers; its original

purpose was to transport grain, and it was later used for wine, timber, and other products.

1706: In Britain, Parliament passes the first statute creating a Turnpike Trust to construct and oversee the country's roads and to levy tolls on vehicles traveling on them.

1755: In the United States, George Washington acquires Conestoga wagons to transport military goods; the principal design innovation of the Conestoga wagon, the curved floor that helps keep the contents from shifting, also made it a popular wagon for settlers crossing the American continent to settle in the West.

1758: In England, the Middleton Railway in Leeds is established by an act of Parliament, lending credence to its claim to be the oldest public railway in the world.

1774: The Scottish engineer and inventor James Watt builds an efficient, stationary steam engine, used at first to operate plumps and later for many industrial purposes.

1784: In England, postal service by horse-drawn coach is introduced; the first postal run was from Bristol to London, but service was quickly expanded to include other cities, including Edinburgh in 1786.

1789: The U.S. Congress appropriates funds for lighthouses, buoys, and beacons and federalizes the lighthouses already existing.

1790: In Scotland, the Forth and Clyde Canal opens, crossing the Scottish mainland and linking the Firth of Forth with the Firth of Clyde.

1806: In the United States, legislation authorizing construction of the first federal highway, the National Road connecting Ohio with the Atlantic Coast, is signed by Thomas Jefferson.

1807: In the United States, Robert Fulton launches the first successful commercial steamboat, the *Clermont*, on the Hudson River, where it carries passengers between New York City and Albany, a distance of about 150 miles.

1813: The first successful steam locomotive, the "Puffing Billy" designed by William Hedley, begins operation at the Wylam colliery near Newcastle on Tyne, England.

1817: In Germany, Baron Karl von Drais invents a "walking machine" that resembles a bicycle without pedals or a chain; it consists of two wheels in a wooden frame and was used by straddling the frame, pushing off against the ground with your feet, and gliding.

1825: In the United States, the Erie Canal begins operation, providing the first water link between the Hudson River and the Great Lakes, thus allowing goods to be transported from the Atlantic Ocean into the central United States without having to be carried overland; the first ship to use the canal, a packet boat named the *Seneca Chief*, departs from Buffalo, New York, on October 26 and arrives in New York City on November 4.

1825: In England, the first steam-powered railway service begins operation between Stockton and Darlington.

1827: In New York City, Abraham Brower establishes the city's first public transportation service along Broadway, provided by a 12-seat stagecoach that followed an established route and charged a set fare to passengers.

1827: In New York City, the banker John Mason organizes a street railway with horse-drawn vehicles and cars running on metal tracks; the cars are built by John Stephenson, who becomes a major supplier of horse-drawn streetcars.

1828: In Germany, the horse-drawn Prince William Railway begins operation to haul coal; it begins carrying passengers in 1833 and, in 1847, begins using steam power.

1830: George Stephenson begins operating a passenger railway between Manchester and Liverpool.

1832: In Sweden, the Göta Canal is completed, forming part of a waterway reaching from the Atlantic Ocean to the Baltic Sea.

1832: The *Sirius* becomes the first steamship to cross the Atlantic; the journey takes nine days.

1840: The first contract to transport mail across the Atlantic Ocean by steamship is granted to Samuel Cunard.

1843: Completion of the Thames Tunnel under the Thames River in London; used originally for pedestrians, it later was used as a railway tunnel.

1847: Great Britain becomes the first country to adopt standard time zones, motivated by the growth of the rail system and the need to have a standard method of keeping time to facilitate accurate timetables.

1849: Public transportation begins in Toronto in the form of horse-drawn omnibuses designed by cabinetmaker Burt Williams and operating along King Street and Yonge Street.

1852: In Chicago, omnibuses begin providing public transportation; the first buses were horse-drawn stagecoaches that took passengers between rail stations.

1853: The first passenger railway in India begins operation, running from Bombay to Thane; several previous railways were already in operation but were used to transport materials rather than passengers.

1854: A steam railway begins operation in Victoria, running from Flinders Street to Sandridge; routes were soon added running to St. Kilda (1857), North Brighton (1859), and Essendon (1860).

1859: The first street railways in Chicago begin operation; the cars are horse-drawn omnibuses with steel wheels and run on rails attached to the plank streets.

1861: In Toronto, the first horse-drawn street railways begin operation along King Street, Yonge Street, and Queen Street.

1862: In the United States, President Abraham Lincoln authorizes construction of the

Transcontinental Railroad (completed in 1869) by signing the Pacific Railway Act.

1863: The first underground railway begins operation in London, running from Padding to Farringdon Streets.

1864: In England, construction of the Clifton Suspension Bridge begins; designed by Isambard Kingdom Brunel, the bridge spans the River Avon and the Avon Gorge.

1865: The velocipede, or “Boneshaker,” an early proto-bicycle, is introduced; originally made entirely of wood, it has pedals attached directly to the front wheel.

1869: In Egypt, the Suez Canal at Port Said opens.

1869: In London, the East London Railway begins running steam trains through the Thames Tunnel.

1869: The American engineer George Westinghouse invents the railway air brake, replacing manual systems and greatly increasing the safety of rail travel; Westinghouse makes many improvements to the air brake over the years, and in 1893, the U.S. federal government requires automatic air brake systems on all interstate rail travel.

1869: In Melbourne, Australia, the city’s first public transportation fleet begins operation, as the Melbourne Omnibus Company begins operating 11 horse-drawn buses; by 1881, the fleet had expanded to 158 horse-drawn buses.

1869: In the United States, the transcontinental railroad is completed when the Union Pacific and Central Pacific Railroads meet at Promontory Summit in Utah.

1870: Elevated rail service begins in New York City, running along Greenwich Street and Ninth Avenue in Manhattan.

1870: The first all-metal bicycles are created, with pedals attached directly to the enlarged front wheel and solid rubber tires, which provided a smoother ride. One model, built by James Starley,

is called the penny farthing bike because of the different sizes of the two wheels.

1879: A French team, led by Ferdinand de Lesseps, begins construction on the Panama Canal.

1879: Sandford Fleming, a Scottish-born engineer working in Canada, popularizes the concept of standard world time zones, including establishment of the prime meridian at Greenwich, England, the location still used today.

1880: In the United States, the League of American Wheelmen, an organization of cyclists, is formed and lobbies for better roads.

1881: In Dunedin, New Zealand, the first cable tram line outside America begins operation; designed by George Smith Duncan, it begins operation with a single line, with a second added in 1883.

1883: A cable-powered railway begins providing service in New York City, running over the Brooklyn Bridge between Manhattan and Brooklyn.

1884: Thomas Stevens rides a bicycle across the United States from Oakland, California, to Boston, Massachusetts.

1885: In Melbourne, Australia, the city's first cable tram line begins operation; by 1891, a network of 17 miles of cable trams connected Melbourne with its surrounding suburbs, and the system remained in operation until 1940.

1885: The first automobile, the three-wheel Tri-Star, is built by the German engineer Karl Friedrich Benz; it is powered by an internal combustion engine.

1885: The German engineer Gottfried Wilhelm Daimler builds the first successful four-wheeled automobile; like the Tri-Star, it has an internal combustion engine.

1888: In Germany, members of the Benz family of automobile manufacturers drive a car 90 kilometers, from Mannheim to Pforzheim, to demonstrate the usability of the new vehicles.

1889: Bicycles begin using pneumatic rubber tires, creating a smoother ride.

1890: A cantilevered railroad bridge is built across the Firth of Forth in Scotland.

1890: In London, the City and South London Railway begins operation of the first deep-level electric tube railway in the world; it runs between Stockwell and King William Street, and station access is provided by a hydraulic lift.

1890: In Russia, work begins on the Trans-Siberian Railway.

1890: In Potsdam, German Otto Lilienthal begins making guided flights in a glider.

1892: In Toronto, the Toronto Railway Company is granted a 30-year franchise over the city's streetcar system and begins operating electric streetcars; by the end of 1894, electric cars have completely replaced the horse-drawn variety.

1893: The modern bicycle frame design, with its diamond shape, is introduced.

1897: In Chicago, the El, or elevated train service, begins operation in the central downtown area, called the Loop; the elevated train tracks allowed them to bypass the congested streets of Chicago.

1897: In Berlin, eight automobiles are exhibited at the first International Motor Show.

1898: The American woman's rights advocate Susan B. Anthony cites the bicycle as an important force in the liberation of women as the popularity of the bicycle encouraged simpler clothing styles while also increasing mobility.

1898: The Canadian American sailor Joshua Slocum becomes the first person to make a solo voyage around the world, a trip publicized in his 1900 book *Sailing Along Around the World*.

1900: In Illinois, the Sanitary and Ship Canal begins operation, reversing the flow of the Chicago River and bringing water from Lake Michigan to dilute the sewage of Chicago.

1900: In the United States, only one in 9,500 citizens owns a car, and only 22 percent of those run on internal combustion engines, with most of the rest being powered by electricity or steam.

1900: The first line of the Paris Metro begins operation, running from the Porte de Maillot to the Porte de Vincennes and providing transportation to the summer Olympic Games being held in Paris that year; 30,000 Metro tickets were sold on the first day of operation.

1901: In the United States, Samuel Pierpont Langley builds the first aircraft to be powered by an internal combustion engine.

1901: C. L. Horock designs the first modern shock absorber, the so-called telescope, which uses a piston with a one-way valve and air or oil to resist movement.

1902: In France, the industrialist Louis Renault introduces drum brakes for automobiles.

1902: In France, Leon Serpollet drives a steam car at 75 miles per hour, setting a land speed record. Shortly afterward, the record is broken by William K. Vanderbilt driving an internal combustion car; Vanderbilt reaches the speed of 76 miles per hour.

1903: Horatio Nelson crosses the United States by automobile in 65 days.

1903: In the United States, Wilbur and Orville Wright complete four sustained flights with a powered, controlled aircraft; the longest flight covers 852 feet.

1904: In Germany, Ludwig Prandtl presents a paper describing the concept of an aerodynamic boundary layer.

1904: The United States becomes the world's leading automobile manufacturer, surpassing France.

1904: The Interborough Rapid Transit (IRT) Company begins operating the first official subway system in New York City, with 9.1 miles of track running from city hall in downtown

Manhattan to 145th Street. The IRT gradually expands service to the other bureaus, adding service to the Bronx in 1905, to Brooklyn in 1908, and in 1915 to Queens.

1904: The United States begins work on the Panama Canal, taking over an effort previously abandoned by the French.

1906: In the state of Victoria, Australia, an electric tram line begins running from St. Kilda to Brighton; many more lines were constructed over the next 14 years, and in 1920, they were consolidated under the auspices of the Melbourne and Metropolitan Tramways Board.

1907: The Fifth Avenue Coach Company begins offering the first passenger motor bus service in New York City, running between Washington Square in Lower Manhattan and 90th Street.

1908: In Michigan, Henry Ford begins producing the Model T automobile, with more than 10,000 cars produced in the first year alone.

1908: In London, the three separate companies operating underground railway services begin coordination of their services, including the development of common signage and distribution of free pocket maps.

1910: Commercial air service is provided by the rigid airship *Deutschland*, developed by Ferdinand Zeppelin.

1912: The American aviator Glenn Curtis demonstrates *The Flying Fish*, the first successful flying boat.

1912: The ocean liner *Titanic*, operated by the White Star line, sinks in the North Atlantic on the way from England to America, killing more than 1,500 people.

1913: In December, the Panama Canal is completed, creating an unbroken waterway between the Atlantic and Pacific Oceans.

1913: The first subway in Latin America begins operations in Buenos Aires, Argentina.

1913: In Michigan, Ford Motor Company develops the first moving assembly line for automobile production, allowing cars to be made more cheaply and efficiently.

1914: In New York, Lawrence Sperry demonstrates the use of an automatic gyrostabilizer to keep an airplane level and on a straight course.

1915: In the United States, the National Advisory Committee for Aeronautics is created to foster and support aeronautical research.

1915: In New York City, the Brooklyn Rapid Transit Company begins offering subway service between the boroughs of Manhattan and Brooklyn; it will be taken over by the Brooklyn-Manhattan Transit (BMT) Corporation a few years later.

1916: In the United States, the Federal Aid Road Act becomes law, creating a program in which the federal government provides funding to the states to construct roads to facilitate mail delivery.

1918: Airmail service in the United States begins, with a flight from Washington, D.C., to New York City.

1919: U.S. Navy pilots cross the North Atlantic Ocean, from Newfoundland to London, making stops in the Azores and Lisbon.

1919: In Europe, the first air passenger service begins across the English Channel between London and Paris.

1920: The New York City subway system begins using coin-operated turnstiles rather than tickets; a ride first cost a nickel and was later raised to a dime.

1923: In the United States, construction begins on the Lincoln Highway, the first fully paved road to cross the United States; it will run through 13 states (14 after rerouting) on its course from New York City to San Francisco.

1924: In the United States, the National Conference on Street and Highway Safety, hosted by

Secretary of Commerce Herbert Hoover, brings together engineers, automobile manufacturers, and insurers to seek ways to reduce the number of deaths caused by automobile accidents.

1926: In the United States, Francis Wright Davis introduces the first power steering system in a Pierce-Arrow automobile.

1927: In May, American Charles Lindbergh makes the first nonstop solo flight across the Atlantic Ocean from New York to Paris.

1927: One out of every seven Americans owns a car.

1927: In June, Lester Maitland and Albert Hegenberger complete the longest open-sea flight to date, flying 2,400 miles from Oakland, California, to Honolulu, Hawai'i.

1932: American aviator Amelia Earhart becomes the first woman to fly solo across the Atlantic from Newfoundland to Ireland.

1932: The City of New York creates the Independent Rapid Transit (IND) railroad, the first city-owned subway line.

1933: The first commercial airliner, the Boeing 237, is introduced; it has two engines, variable-pitch propellers, and retractable landing gear and seats 10.

1933: In London, Harry Beck creates a diagram map for the Underground that remains in use, with modifications, to this day.

1934: The French *Citroën Traction Avant* becomes the first successful, mass-produced front-wheel-drive automobile.

1934: Germany begins construction on the first *autobahn*, or freeway; the first section, running from Frankfurt to Darmstadt, opens in 1935 and is so well-constructed for high speed travel that it is used for racing as well as transportation.

1935: The first subway system in the Soviet Union, the Moscow Metro, begins operation.

1935: The British engineer Robert Watson-Watt patents the first practical radar system; originally intended to study the weather, it proves useful in detecting incoming aircraft during World War II.

1935: In November, Pan American Airways begins the first transpacific airmail service between Manila and San Francisco.

1936: In October, Pan American Airways begins operating the first transpacific passenger air service.

1937: The jet engine is designed independently in England, by Frank Whittle, and Germany's Hans von Ohain.

1937: The German passenger airship Hindenburg catches fire in New Jersey, killing more than 30 people and shattering public confidence in rigid airships as a means of transportation.

1937: Amelia Earhart disappears somewhere in the Pacific during an attempt to fly around the world.

1939: The VS-300 helicopter, one of the first practical single-rotor helicopters, is designed for the U.S. Army by the Russian émigré Igor Sikorsky.

1939–45: In London, Underground Tube stations provide shelter from bombing raids and are also used as military command centers and for the storage of artworks.

1940: In the United States, engineer Karl Pabst designs the Jeep, which becomes a workhorse vehicle for the United States and allied forces in World War II.

1940: In Washington State, the Tacoma Narrows suspension bridge collapses into Puget Sound less than five months after it began carrying traffic; the collapse was caused by periodic motion or flutter caused by the wind.

1940: New York City purchases the Brooklyn-Manhattan Transit (BMT) and the Independent Rapid Transit (IRT) Corporations and becomes

the sole owner and operator of subway and elevated trains in the city.

1942: The Alcan, or Alaska–Canada, Highway, constructed largely as a military supply route during World War II, is completed; it runs from Dawson Creek, British Columbia, to Delta Junction, Alaska.

1945: In Wolfsburg, Germany, the first Volkswagen Beetle is manufactured; production of the Beetle continues until 2002.

1945: The Chicago Transit Authority (CTA) is created, bringing Chicago's mass transit systems under public ownership for the first time. By 1997, the CTA manage a system carrying 287 million riders annually on buses and 130 million on rapid transit cars.

1947: In California, U.S. Air Force pilot Charles Yeager becomes the first to fly faster than the speed of sound, that is, breaking the sound barrier.

1948: During the Cold War, Russia blocks surface access to the Allied sector of Berlin, Germany; in response, the Allies organize the Berlin Airlift to transport food, fuel, and other necessities to the city's residents by airplane.

1950: The *St. Roch*, a Canadian ship, becomes the first to circumnavigate North America, passing through both the Panama Canal and the Northwest Passage.

1952: The first commercial jet airline service, between London and Johannesburg, South Africa, begins operation using the De Havilland Comet.

1952: The American engineer Richard T. Whitcomb discovers the area rule, which becomes a fundamental aspect of airplane design.

1953: The New York City subway system begins using tokens, as the fare had risen to 15 cents and the turnstiles could only handle one type of coin.

1954: In the United States, the Wiley–Dondero Act creates the Saint Lawrence Seaway Development Corporation to develop the U.S. portions

of the Saint Lawrence Seaway between Lake Erie and Montreal.

1955: The last elevated public transit rail line closes in Manhattan, New York City, the Third Avenue El.

1956: The New York City Transit Authority shuts down its last two trolley lines, which ran in Brooklyn along McDonald Avenue and Church Avenue.

1956: In the United States, Congress passes the Interstate Highway Act to create a national system of limited-access, high-speed highways.

1957: In East Germany, the first Trabant, an automobile with a two-stroke engine, is produced; it becomes the most common car in East Germany and remains in production until 1991, when East and West Germany are reunified.

1960: The New York City Transit Authority ceases operation of the last trolley buses in the system.

1960: One in three Americans owns a car.

1962: The Trans-Canada Highway is completed, running from the Atlantic to the Pacific coasts and connecting all 10 provinces.

1962: Colorado businessman Leonard Rivkin introduces the first child car safety seat, called the Strolee National Safety Car Seat for Children.

1963: Positive crankcase ventilation (PCV) is introduced to automobile engines in an effort to reduce the emission of harmful gases.

1964: In California, construction begins on the Bay Area Rapid Transit (BART) system; in 1972, the first segment of the system, a 28-mile stretch between Fremont and MacArthur stations, begins operation.

1964: In the United States, the Urban Mass Transportation Act creates a program of matching federal grants to help states build urban mass transportation systems.

1964: In Japan, the first of the high-speed *Shinkansen*, or bullet train rail lines, begins operation, running from Tokyo to Osaka.

1965: New York City begins express bus service, with a line running from Staten Island to Brooklyn.

1965: The United States begins developing high-speed train service for the densely populated Northeast Corridor, authorized by the High Speed Ground Transportation Act of 1965.

1965: The U.S. Congress passes the Vehicle Air Pollution and Control Act to regulate automobile emissions.

1966: In the United Kingdom, an efficient electronic fuel injection system is developed for automobiles.

1967: In the United States, 46 people are killed when the Silver Bridge, running between Gallipolis, Ohio, and Point Pleasant, West Virginia, collapses; this accident helped motivate the inclusion of national standards for bridge inspection in the 1968 Federal Aid Highway Act.

1969: The Boeing 747, the first jumbo jet, or wide-body commercial airplane, begins operations.

1969: In Washington, D.C., construction begins on an underground rapid-transit rail system, known as the Metro; the first line begins operation in 1976, and the system is later extended to include parts of Maryland and Virginia.

1969: In New York City, reduced transit fares for senior citizens are introduced, a benefit extended in 1975 to disabled people as well.

1969: In the United States, high-speed Metroliner rail service between Washington, D.C., and New York City begins operation; the Metroliner service continues until 2006, when it is replaced by the Acela Express service.

1970: On April 22, the first Earth Day is held, reflecting growing interest in conservation and environmentalism, including the development

and expansion of public transportation systems and other alternatives to the automobile.

1971: In Melbourne, Australia, construction begins on an underground rail loop; a test train ran through it in December 1980, and regular passenger service began in January 1981.

1973: The Paris Metro system introduces turnstiles, replacing the system of punched paper tickets that had been used from the system's opening in 1900.

1976: In January, commercial service begins on the Concorde SST, a plane capable of flying at twice the speed of sound and making the trip from London to New York in 3.5 hours.

1977: Airplanes operated by KLM and Pan Am collide on a runway in Tenerife (the Canary Islands, Spain), killing 583 people in the deadliest accident in commercial aviation history.

1978: In the United States, the Airline Deregulation Act of 1978 liberalizes several aspects of air travel, including allowing airlines to reduce fares without needing the approval of the Civil Aeronautics Board and allowing new airlines to begin service on routes not protected by other carriers; however, smaller communities are guaranteed essential air services for an additional 10 years, with government subsidies if the routes are unprofitable.

1979: The Iranian Revolution disrupts oil production and exports from Iran, causing higher gasoline prices and shortages in the United States and increasing interest in fuel-efficient vehicles as well as alternative means of transportation; one response is Executive Order 12191, signed by U.S. President Jimmy Carter, which encourage federal employees to carpool to work.

1980: Japan becomes the world leader in automobile manufacturing, surpassing the United States.

1981: The first mass-produced mountain bike is introduced in the United States, helping popularizing mountain biking as a sport.

1981: In France, the first high-speed train service (*Train à Grand Vitesse*) begins operating between Paris and Lyon.

1981: In the United States, the Professional Air Traffic Controller's Association (PATCO) goes on strike; when most members refuse to return to work (government unions in the United States are not allowed to strike), President Ronald Reagan fires them, and PATCO is decertified by the Federal Labor Relations Authority.

1982: Braniff Airlines becomes the first U.S. scheduled airline in history to file for Chapter 11 bankruptcy protection; an administrative law judge later determines that Braniff's financial collapse was caused in part by the Airline Deregulation Act.

1984: New York becomes the first U.S. state to mandate the use of seat belts in automobiles for all passengers.

1985: The U.S. cyclist John Howard becomes the first person to break 150 miles per hour on a bicycle, achieving a speed of 152.3 miles per hour.

1987: In London, fire and safety regulations are upgraded after 31 people are killed in a fire caused by an escalator at the King's Cross Underground station.

1987: The European Commission introduces the first reforms intended to liberalize air transport among member countries, limiting the right of governments to determine air fares and giving airlines more flexibility to share seat capacity.

1988: Pan American Flight 103 blows up over Lockerbie, Scotland, killing 270 people; a British investigation later determines that the cause of the explosion was probably a terrorist bomb hidden in a radio-cassette player, and in 1991, two Libya intelligence agents are indicted for this crime.

1990: California passes the Zero Emission Vehicle Mandate, requiring 10 percent of the state's cars to produce no emissions by 2003, and 2 percent by 1998.

1991: In the United States, the Intermodal Surface Transportation Efficiency Act (ISTEA) emphasizes regional transit planning and gives states greater flexibility in planning mass transportation; it also mandates airbags as a safety feature in automobiles.

1992: In the United States, the Energy Policy Act encourages the development of automobiles powered by alternative fuels, including natural gas, battery power, and mixtures of gasoline and alcohol.

1993: The New York City Transit Authority introduces the MetroCard, an electronic-stored value card; it is gradually phased in throughout the system, and by 1997, the entire subway and bus system accepts MetroCards.

1993: In the United States, air traffic controllers fired after the 1981 strike are allowed to reapply for employment with the Federal Aviation Administration.

1995: In Tokyo, members of the Aum Shinrikyo cult release sarin gas on the Tokyo Metro, an act of domestic terrorism resulting in 13 deaths.

1996: General Motors begins producing the EV1, a mass-produced electric car; it ceases producing the EV1 in 1999.

1997: The European Commission introduces *cabotage* in the air transport sector, giving an airline from one member state the right to operate an air route within another member state.

1997: Toyota introduces the first commercial, mass-produced hybrid automobile, the Prius, and sells nearly 18,000 vehicles in the first year.

1998: The New York City Transit Authority begins using hybrid electric buses.

1999: The United States hands over sovereignty of the Panama Canal to Panama, fulfilling the terms of the Torrijos–Carter Treaties signed in the 1970s by U.S. President Jimmy Carter and General Omar Torrijos of Panama, which replaced the original agreement of 1903 between the countries.

2001: A coordinated series of terrorist attacks on the United States, including the World Trade Center in New York City and the Pentagon near Washington, D.C., all involving hijacked commercial air flights, spur the creation of the Transportation Security Administration (TSA) in the United States.

2003: In the New York City public transportation system, tokens are no longer accepted as of April on subways, and as of the end of the year on buses, as they have been replaced by the electronic stored-value MetroCard.

2004: In Shanghai, China, the first commercial maglev (magnetic levitation) train begins operating, running from the Longyang Road metro station to Pudong airport.

2005: In London, 52 people are killed in coordinated suicide bomb attacks on a bus and three Underground trains.

2005: The Airbus A380, the world's largest passenger aircraft, begins operation; it can carry more than 850 passengers.

2007: Panama begins a project to widen the Panama Canal and create new locks in order to accommodate larger ships, with completion scheduled for 2014.

2007: The case of an Atlanta lawyer draws attention to the possibilities of communicable disease being spread rapidly through modern transportation systems. The man, Andrew Speaker, had multidrug-resistant tuberculosis, yet took several international airplane flights, potentially exposing other passengers to the disease; upon return to the United States, he was placed in involuntary isolation (quarantine) for treatment.

2009: Nissan introduces the LEAF, an electric car that can travel 90 miles per hour and has a range of 100 miles on a full battery charge; the acronym stands for Loading, Environmentally friendly, Affordable, Family car.

2010: In Moscow, about 40 people are killed in two Metro stations as a result of suicide attacks.

2011: Somali pirates working in the Arabian Sea kill four American hostages, bringing increased attention to the problem of sea piracy and calling for stronger measures in response to the problem.

2012: A study by the Highway Data Loss Institute finds that the probability of accidents is reduced in cars that have a forward collision-avoidance system installed; adaptive headlights are also associated with reduced probability of accidents, but lane departure warning systems are not.

2012: In China, the world's longest high-speed rail line begins regular service from Beijing to Guangzhou; the trains travel the roughly 1,200-mile distance in about eight hours, while regular trains on a parallel track require 21 hours to complete the same route.

2012: A study by the Norwegian University of Science and Technology suggests that the environmental benefits of electric cars, as compared to gas-fueled cars, are not as great as previously assumed; among the causes were greater toxic waste produced by electric car factories and the use of toxic minerals in producing the car batteries.

2012: The U.S. Federal Aviation Agency releases a forecast predicting that, as measured by Revenue Passenger Miles (RPM), airline passenger travel will nearly double by 2032.

2012: The first private cargo rocket to supply the International Space Station is launched from Cape Canaveral, Florida; the rocket is built by the Space Exploration Technologies Corporation (SpaceX) and is part of a National Aeronautics and Space Administration (NASA) program to replace government-operated spacecraft with those operated by private companies for low-Earth orbit missions.

2012: The final report on a 2009 Air France plane crash killing 228 people attributes the crash to a combination of confusing alarm systems, faulty equipment, and lack of pilot training for the particular circumstance encountered (a high-altitude stall).

2013: In India, about 40 people are killed at the Allahabad railway station in an incident

described as a stampede caused by an overload of passengers (many of whom were pilgrims traveling to a religious festival), delayed rail service, and a sudden change in the routing of a departing train, causing several thousand people to surge onto a footbridge meant to accommodate fewer than 1,000.

2013: Mercedes Benz exhibits an electric car, the Mercedes Electric Drive, that has a quick-charge feature allowing it to travel 60 miles after being charged for two hours; the Electric Drive, which was developed in cooperation with Tesla Motors, is scheduled to go on sale in 2014.

2013: In the United States, federal budget cuts lead the Federal Aviation Administration to announce the closing of 149 air traffic control towers; several airports, including the Spokane International Airport and the Central Illinois Regional Airport, file lawsuits arguing that the closings would cause dangerous conditions.

2013: The Metropolitan Transportation Agency in New York City announces that almost \$5 billion will be required to repair damage caused by Hurricane Sandy, which hit the city in October 2012.

2013: In its "Global Status Report on Road Safety 2013," incorporating data from 182 countries, the World Health Organization reveals that worldwide 1.24 million road traffic deaths occur annually, making road traffic injuries the leading cause of death among people aged 15 to 29 years.

2013: In May, the World Bank releases a report concluding that production of crops for biofuel has only a limited effect on food prices.

2013: On July 3, Asiana Airlines Flight 214 crashed during its approach to San Francisco International Airport. Of the over 300 passengers on board, two died at the scene and 181 were injured.

2014: On March 8, Malaysia Airlines Flight 370, carrying over 200 passengers and 12 flight crewmembers, went missing during a scheduled flight from Kuala Lumpur to Beijing. Despite extensive

searches, as of June 2014, no trace of the plane has been found.

2014: On April 10, the European Commission issues its first-ever EU Transport Scoreboard, comparing member states on 22 categories, including safety, environmental impact, and infrastructure for road, rail, water, and air transportation.

2014: On May 7, the U.S. Department of Transportation issues an Emergency Restriction Prohibition Order requiring rail carriers transporting large amounts of crude oil from the Bakken shale formation to notify counties in each state through which the crude oil will be moved. This requirement was prompted by several accidents

involving the volatile Bakken crude oil, including an explosion in Quebec that killed 47 people.

2014: On June 23, a group of electric car advocates led by the Illinois Green Economy Network begins a 500-mile drive across Illinois to counteract range anxiety (the fear that an electric car will run out of power before reaching a charging station). The drive, which began in Carbondale and ends in Grayslake, includes stops at 11 Illinois community colleges that have charging stations.

Access Roads

Access roads represent the most fine-grained connections within an urban street network. They generally provide direct, local access to individual lots and feed into the arterial road network. On these bases, development will generally front rather than turn its back on access roads. Access roads generally assume a simple, undivided cross section, with regular lot access and low traffic speeds being primary considerations. These compare to higher order roads that assume more complex geometries, are often wider, and limit direct lot access in favor of higher travel speeds and longer trips.

Access roads feed into these higher order roads (often called distributors or connectors), which span and link adjacent neighborhoods, much like streams feed main tributaries within a river system. These higher order roads, in turn, can feed into the primary or arterial road network, which is typically characterized by higher speed limits, significantly increased carrying capacity, and much less local accessibility. This sort of hierarchical system was embraced in North America and Australasia during the post–World War II boom in road building, motorization, and suburbanization. Elements of this system have also been adopted elsewhere, but historical, less hierarchical street networks are more apparent in geographies such as western Europe, while relatively disorderly transport and

land use planning in many Asian cities has also produced less hierarchical systems.

Form and Function

The width of access roads varies depending on context. However, a functional width of 18 feet (5.5 meters) for two-way and 11 feet (3 meters) for one-way vehicle flows is appropriate. Added width may be required depending on the types of vehicles that will use the road: wider carriageway is necessary in industrial areas. Depending on carriageway width, two-way roads may permit two vehicles traveling in opposite directions to pass. Narrower access roads have to function as yield streets, requiring passing areas. Passing areas are usually facilitated through intermittent gaps in on-street parking.

The use of a road by a particular mode of transport depends on the functional hierarchy, urban location, and land use situated along the road. Access roads are often intended to facilitate use by a variety of transport modes, with particular emphasis on pedestrian activity. It can be expected that more pedestrian activity will occur within residential land use cells (particularly where shops and open space are accessible locally) than within non-residential (that is, industrial) precincts. Despite this expectation of use by pedestrians, many residential access roads have been constructed without footpaths, or sidewalks. This can create difficulties for all potential pedestrians and particular problems

A series of narrow access roads, enhanced by landscaping and several small- and medium-sized roundabouts, surround this shopping center and its parking lot in Málaga in southern Spain. Roundabouts, often seen on busier access roads, may serve dual purposes of both managing vehicle movements on different approaches and fostering traffic calming.

for the mobility and visually impaired. The lack of pedestrian facilities along access roads can reflect low anticipated walking demand.

Aside from footpaths in some circumstances, access roads rarely incorporate specific design responses in support of facilities for pedestrians, cyclists, or public transport. This is because access roads represent the bottom rung in a road hierarchy and, in theory, attract relatively low traffic volumes at relatively slow speeds. Cyclists are expected to use the carriageway, while transit services are more likely to use higher order roads rather than access roads except for short distances. Moreover, the carriageway width and swept paths required by buses can compromise objectives relating to safety and speed mitigation, thereby adding to the case for transit to be routed via higher order roads.

Other Design Characteristics

Depending on their location within the urban fabric and local design prerogatives, access roads

can incorporate additional, nontransport features. Often, service infrastructure (water, sewerage, and power) needs to be accommodated either above or below ground. In newer developments, most services may be located below ground within the road shoulder. However, some older access roads may have service infrastructure located below ground within the roadway, hence the ubiquitous manhole covers that can be found in cities like New York and Paris.

Street furniture in the form of signage, street lighting, and seating are further encumbrances within a typical access road cross section. Highly urbanized areas such as town centers generally reflect a higher density of street furniture compared to a typical residential area.

Soft landscaping is common in residential areas and less so in constrained, highly urbanized environments where space is at a premium. In urbanized areas the landscaping response may be in the form of hard landscaping, such as paving, stone,

and metals. On-street parking provisions may range from parallel curb parking to parking bays depending on cross-section widths and local parking requirements.

Drainage functions may be hard-engineered into street designs through provision of curbside gutters. Alternatively, “soft” drainage infrastructure may be collocated with landscaping in the form of swales.

In short, there is no common design for access roads. Rather, design responses should and typically do support local functional requirements and safety and amenity objectives.

Capacity and Speed

The capacity of an access road is influenced by the posted speed limit, general design characteristics such as road width and geometric characteristics, density of intersections, and lot access spacing. The practical capacity of a typical single carriageway road—two-way and wide enough for two vehicles to pass relatively comfortably—is approximately 15,000 vehicles per day or 1,500 vehicles per hour in the peak.

A much lower threshold can both apply to and be desirable for many access roads, particularly within residential areas. For example, above about 5,000–6,000 vehicles per day, direct lot access becomes difficult to manage (and can be hazardous), especially where vehicles need to back out into the carriageway because of the reduced frequency and generally reduced gaps in traffic along the access road. Under these circumstances, special provisions may be needed to enable protected reversing maneuvers. Moreover, the presence of higher levels of traffic (more than 6,000 vehicles per day) within residential areas generally results in environmental degradation when considered from a noise or vehicle emissions perspective.

Posted speed limits that apply to access roads depend on where they are located within the urban fabric and the land uses they serve. In inner urban and dense residential areas, speed limits of 20–25 miles (30–40 kilometers) per hour may apply. In Australian cities, in suburban locations, a 30 mile (50 kilometer) per hour limit is typical. In outer industrial areas, a slightly higher speed limit (for example, 60 kilometers or 35 miles per hour) may apply. Generally, the speed limit should reflect the density of activity along the access road (including

frequency of property accesses and nonvehicle activity such as walking and cycling).

The design speed limit of a road can vary greatly from the posted speed limit. Generally, the following design elements influence actual travel speeds:

- Lane width
- Midblock pedestrian and bicycle crossings
- Block length
- Provision of on-street parking, given it can create friction along the carriageway
- Landscaping treatments, including how dense they are and whether they are planted up to the curbline
- Development setbacks
- Any vertical or horizontal deflections

In principle, more visually and physically constrained carriageways produce stronger cues for drivers to manage their speeds.

Chicanes, traffic islands, speed tables and the like are typical devices constructed along access roads to deflect vehicles from straight, uninterrupted paths of travel and thereby manage traffic speeds. As isolated treatments, they can also dissuade through traffic from particular routes due to the inconvenience of negotiating them. In many cases they are retrofitted to roads when it becomes evident that traffic speeds and/or flows exceed desirable limits. In extreme circumstances, access-road connections (through roads) may be turned into culs-de-sac to reassign nonlocal traffic on to other more favorable routes.

Intersections

Intersection density along access roads is relatively high, with planning ordinances in many cities stipulating maximum block lengths. This befits access roads being at the bottom of a functional hierarchy of roads.

Intersection treatments can vary depending on the form and function of cross streets. In some cases, there is no regulatory signage, even at four-way junctions. This transfers all responsibility to drivers to negotiate the intersection and, arguably, compels drivers to take care on approach because of the uncertainty of the behavior of other motorists.

Priority control treatments—yield (give way) and stop signage—are common. These typically apply to the minor, less trafficked, approaches, and direct

motorists to yield right of way. At busier intersections, small roundabouts may be installed. These can serve dual purposes: managing vehicle movements on all approaches and acting as a traffic calming device.

It is rare for traffic signals to be constructed on access roads, except where a road intersects with a major (arterial) road, where, without such a treatment, vehicles would have insufficient opportunities to turn into or out of the minor approach or approaches. Often, such a high-order treatment is installed only when there are no alternative routes into an urban area or the access road has some other strategic importance.

The alternative is to restrict movements onto and from the access road through installation of engineering devices such as “seagull islands.” This is to prevent risky turning maneuvers that can evenuate when there are few gaps in traffic and drivers get frustrated. In locations such as Britain, India, Japan, and Australasia, where people drive on the left-hand side of the road, right-turning movements are often banned in these circumstances. In North America, continental Europe, and China, where people drive on the right, left-turning movements are banned.

New Planning Paradigms

Strategies to mitigate and manage traffic speeds and volumes along access roads have strong political and planning bases. Speed management is understandable where there is a high frequency of crossing movements and movements to and from individual lots. Within residential neighborhoods, there can also be significant pedestrian and cycling activity, and roadways can double as spaces for recreation and play. These functions cannot be reconciled with higher traffic densities and speeds.

Nevertheless, the local connectivity and network permeability that should characterize access roads can be undermined where curvilinear street designs, culs-de-sac, and local area traffic management devices are employed to dissuade through traffic and deliberately isolate specific urban cells. Such street designs have been popular in new tract-housing developments in many North American and Australian cities. For example, Radburn-style design promotes disconnected street networks and isolated urban cells and may be explored in detail in Peter Hall’s *Cities of Tomorrow* (2002). These

outcomes can reinforce car dependence and urban sprawl by increasing distances between origins and destinations, thereby reducing opportunities for people to utilize modes of transport other than cars.

Some neotraditional planning movements, such as North American New Urbanism, challenge the road hierarchy concept and decision making that reduces the connectivity of the street network. This is for a variety of reasons, but crucially, New Urbanists posit that a hierarchical design helps reinforce an overemphasis on the needs of private motor vehicle users. A resource that explores these issues is *Suburban Nation: The Rise of Sprawl and the Decline of the American Dream* by Andrés Duany, Elizabeth Plater-Zyberk, and Jeff Speck (2000).

Instead, the neotraditionalist approach focuses on density of connections generally in the form of a grid road-network pattern providing a choice of routes to permit reduced distances between homes, jobs, and other destinations. By implication, the local access and activity functions associated with access roads need to be reconciled with some through-traffic movements so that longer trips are not simply funneled to connectors and arterial roads.

On one hand, this approach has the potential to stimulate more urban vitality and vibrancy, which is a core New Urbanist tenet. However, it also poses a practical challenge to the exclusivity and quiet sought by many residential communities.

Accessibility and Mobility

Accessibility and mobility are two of the basic concerns in transportation. Although frequently used as synonymous, these concepts reflect different goals for optimizing travel movement from both a socioeconomic and physical context. These concepts are critical to travel and travel choice, providing useful measures and indicators for analyzing and understanding past and present travel and for shaping future travel. This entry presents a conceptual discussion of the distinction between accessibility and mobility, followed by a description of basic measures and indicators, and a brief overview of recent developments worldwide of mobility and accessibility conditions. Finally, special attention is given to the role of these concepts in policy and planning practice.

Conceptual Discussion

From common spoken language to newspaper articles and even to papers of a more scientific nature, accessibility and mobility are commonly used indiscriminately and even as synonymous. Moreover, one can say that in recent years accessibility has even become a trendy concept in both social and political contexts, with accessibility often preferred over mobility independent of the concept being referred to at the moment. In fact, the term *accessibility* has become very common, being one of those terms almost everyone uses (especially in planning and politics) although clear notions of its meaning or of how to measure it are far less common.

Even though both concepts translate a specific ability related to spatial (or virtual) connectivity, they refer to different, although interconnected, abilities. Looking at plain definitions in common

dictionaries, we find the word *mobility* to be the ability to move and the word *accessibility* to be the ability to access or reach. In other words, mobility represents the ease of movement while accessibility represents the ease of reaching desired destinations (opportunities or activities).

The concept of mobility can easily be operationalized through a number of common indicators measuring if, how, and how much travel is performed. Most common indicators measure travel distance, time, frequency (number of personal or freight trips), and mode choice. In contrast, accessibility is a far more ambiguous notion, implying a range of aspects, such as the distribution of potential destinations; the magnitude, quality, and character of activities; the performance of the transportation system; the characteristics of the individuals; and the times at which the individuals are able to participate in activities, among others. Conceptual discussion around accessibility has been somewhat limited. The multidimensional nature of accessibility justifies why several researchers in this field have advocated that the definition of the concept of accessibility depends on the objective for which it is intended. Most common accessibility measures identify areas in equidistance/time of important destinations such as capital cities, city centers, or major transport nodes (isochrones), catchment areas or market areas of important public services or transport nodes, and number or diversity of activities accessible or utility of that access. For more detail on measures and indicators of accessibility and mobility, see below.

Mobility represents the choices people make, while accessibility represents the choices people have, of which only some will actually be made. In this sense accessibility can be regarded as potential for mobility (in short, potential mobility). In fact, mobility or actual travel behavior is an indicator of accessibility but is not a measure of it; that is, high mobility might be an indication of high accessibility, but it is not possible to measure accessibility based on the amount or form of travel.

Measuring Mobility

Mobility indicators provide measures for travel demand, being generally used to identify travel needs and infrastructure congestion or development needs. As stated in the conceptual discussion, the most common indicators of mobility measure

travel distance, time, frequency (number of trips or cargo), and mode choice.

The collection of data for these measures is generally done by resorting to counting and/or travel behavior surveys. Individual data is then aggregated by socioeconomic/demographic groups, by transport mode, by travel purpose, by travel time (in a day, week, month, or year), etc., to develop the analysis of travel patterns. Thus, the general indicators of travel frequency, distance, and time can be presented in any of the above aggregations.

Mobility planning practice may use any of the above indicators and/or resort to mobility-based planning support instruments such as mobility models, transport models, or even land use and transport models.

Measuring Accessibility

Similar to the conceptual discussion around accessibility and mobility, measuring accessibility is again more complex and a less consolidated research field than mobility. However, the theoretical background already provides some baseline concepts, characteristics, and features for measuring accessibility, such as the following:

- Components
- Types of measures (which some authors call “traditions”)
- Operational choices

Although there is no best measure of accessibility, there is a general understanding on the main components of accessibility measures. Accessibility measures generally consist of two basic parts: the land use component (also named activity, motivational, or attraction component) and the transport component (also named resistance or impedance component). The land use component is related to the supply of opportunities. The transport component, like the land use component, is related to the confrontation between supply and demand, in this case, of the transport system. In addition, two further components may be used in accessibility measures: the temporal and the individual components. The temporal component reflects the times at which individuals are able to participate in activities as well as the availability of opportunities at different times of the day. The individual component reflects the characteristics of the individuals, including the

needs (which are dependent on characteristics such as age, life cycle, and lifestyle), abilities (related to physical capacity and specific skills), and opportunities (related to income and travel budgets), depending on individual characteristics. Information and communications technology (ICT) may be considered as the fifth component (when referring to virtual accessibility). Although all of these components have been deemed relevant by one or another publication in the field of accessibility measure, it is generally recognized that it would be difficult to consider all components at once, since it would imply high levels of complexity. Nonetheless, it is important to recognize the implications of excluding one or more of these components when using accessibility measures.

When developing accessibility-based planning support instruments, several accessibility “traditions” are available in the literature. In general, accessibility instruments may be activity based (measuring activities/opportunities accessible) or utility based (measuring the utility of accessing particular activities/opportunities), may be person based or location based (measuring accessibility of people or of places), and/or may be origin based or destination based (measuring accessibility from origins—people or places—or to destinations—people, opportunities, or places). Accessibility instruments may follow one or a combination of these approaches. They may even combine antagonistic approaches, such as combining measures based on origins and measures based on destinations.

Finally, the development of an operational accessibility measure, able to support planning, involves a number of choices from a list of potential features increasing the scientific rigor of the instrument. The following list summarizes several of the most common options to consider incorporating into accessibility measures currently found in the model-building literature:

- Distance decay (simple activity-based measures not considering distance decay and simply summing activities accessible within a specific time limit are generally called “contour measures” or “isochrones measure” or “cumulative opportunity measures”; simple activity-based measures considering distance decay are generally called “potential measures”)

- Competition effects of origins and/or destinations (simple activity-based measures considering the number of activities of the same type or the size of each establishment in accessibility measures are generally known as “gravity measures”; these measures may or not consider distance decay; another example of measures considering competition effects are “inverse balancing factors”)
- Personal or group preferences/constraints (measures including time constraints include the individual component referred to above)
- Trip purposes (considering one specific trip purpose or all trip purposes aggregated versus developing analysis of accessibility per different trip purposes)
- Transport modes (only one transport mode or all aggregated/integrated choosing fastest/cheapest)
- Times of day or days of week/month (measures including time constraints include the temporal component referred to above)

Measures

Some examples of accessibility measures (basic accessibility measure) are isochrones, contour measures, and potential measures.

Isochrones are curves that are equidistant/time from a given origin or destination. The buffers defined by these isochrones identify the physical space one can reach in a given time or distance limit.

Contour measures count the amount of opportunities one can reach within a given time/distance/price limit (also called cut-off) from an origin or destination. Alternatively, contours measure the distance/time/price required to reach a given amount of opportunities from a given origin or destination. The general formulation used for this measure is as follows:

$$A = jO_j \text{ if } d_{ij} \leq L \quad \text{if } d_{ij} > L$$

with A_i : accessibility at origin i ; O_j : opportunities at destination j ; d_{ij} : distance/time/price between origin i and destination j ; L : accessibility limit (cut-off) measured in distance, time or price.

This measure can be used, for example, to identify the population able to reach a primary schools

within five minutes walking time (which represent the potential users of this school), or to identify the number of schools one can reach within five minutes walking from home (which represent the available choices), and so forth.

Potential measures are similar to contour measures; however, they consider distance decay of the importance of opportunities with distance/time/price. The farther away or more cost in reaching an opportunity, the less the influence of that opportunity in the accessibility measure. The general formulation used for this measure is as follows:

$$A = jO_j * f(d_{ij})$$

with A_i : accessibility at origin i ; O_j : opportunities at destination j ; d_{ij} : distance/time/price between origin i and destination j ; $f(d_{ij})$: distance decay function between the origin i and the destination j .

Conceptually, contour and potential measures are very similar using, however, different distance decay functions.

Accessibility planning practice may use any of the above measures and/or resort to accessibility-based planning support instruments. A Web-based online platform for accessibility-based planning support instruments is available at <http://www.accessibilityplanning.eu/accessibility-instruments-2>. This platform presents a number of accessibility instruments developed for planning support, including detailed descriptions on how to use them in practice. An online search engine is also available, enabling the identification of tools regarding operational requirements. Alternatively, a review can be found in a report by scholars Angela Hull, Cecília Silva, and Luca Bertolini, “Accessibility Instruments for Planning Practice.”

Evolution

Urban mobility has undergone significant changes over the past few decades. When referring to passenger mobility, travel distance and frequency have been increasing and the car has become the main means of travel in most European and North American cities, due to its spatial and temporal flexibility. Cargo has also increased exponentially following globalization, with growth across all main transport means (road, air, and sea). In general, it is fair to say that there has been an unprecedented growth in passenger and freight mobility.

Taking a closer look at passenger mobility, several factors have been found to have contributed to this change in travel behavior. The main factors can be summarized as follows:

- Geographical (urban structure) factors (for example, urbanization, suburbanization, car-oriented development, provision of major transport infrastructures)
- Economic, technological, and political factors (for example, globalization, gross domestic product growth, increase of income per capita, cheaper and faster transport modes, increasingly diversified and flexible employment)
- Sociodemographic and cultural factors (for example, increase of population, especially urban population; aging population with better life conditions; change of the role of women in society; smaller households; increase of number of households; rising living standards)

The development of faster and cheaper transport modes has enabled the enlargement of urban areas (urban sprawl) with higher dispersion of households and opportunities, which has, in return, made people more dependent on the car to satisfy daily mobility requirements. The general increase of wealth and income associated with decreasing working hours has enlarged mobility requirements especially for nonwork activities. The rate of work-related trips has decreased considerably, with commuting representing less than half of all journeys in many European and North American countries. Within nonwork trips, which have become the most frequent in large urban areas, leisure trips present the highest travel distance.

While fewer working hours have contributed to more leisure time, social changes have stimulated out-of-home leisure activities, which have been diversifying and therefore contributing to the complexity of travel patterns, which requires higher flexibility from urban transport modes. The household has also experienced many changes, with women having full-time jobs, therefore having fewer children, which are also born later because people tend to marry later in their lives. The whole family has a different structure, higher incomes, and more spare time, which they use for ever-growing

extra activities. Consequently, mobility needs continue to rise and to become more complex due to new travel patterns and extensive urban areas. The travel purposes are less predictable, and those that still are, are losing their share. The private car has been found to provide the required standards (for example, flexibility, accessibility, low cost relative to public transport, high speed) within the contextual change referred to above, having become the dominant travel mode in almost every urban area around the world.

However, increased mobility is not synonymous with increased accessibility. Today, we travel for longer distances than before to reach the same activities. It is true that we have more choices for the same activities, but the variety of activities accessible had but a marginal growth. At the same time, automobile-based mobility has significantly changed our cities as well as the offer of alternative modes. Cities have spread, with a first wave of decentralization of households closely followed by the decentralization of activities. Ever-growing decentralization, enabled by the generalized use of the private car and accelerated road infrastructure provision, has gone well beyond the ability for activity decentralization.

While public and private activities tended to follow urban development (the latter accompanied by public transport expansions and coverage), this is no longer the case. On one hand, low-density development does not provide a competitive market for the development of activities. On the other hand, increased regional accessibility by car still enables businesses to reach dispersed communities without having to move to the neighborhood. Adding to this, public expenditure reductions (due to budget constraints) have also led to concentration of public services using regional car accessibility as grounds for decreasing local service levels.

Regarding supply of transport modes, it is fair to say that public transport has generally improved; however, road infrastructure improvements have, for a long period, been the major political priority. Thus, public transport has been mainly regarded as an alternative for those economically or physically excluded from using the car. There has been a lack of a real comprehensive approach to alternative transport service provision.

As a result of all the phenomena discussed above, increased mobility has, in several cases, also been

responsible for reduced accessibility. For instance, when people with limited access to cars become more distant from desired activities that have decentralized to car-accessible zones, while no alternative public transport modes have been offered or made available, public transport does not provide desired quality standards (regarding comfort, safety, reliability, physical barriers, etc.).

In fact, international and regional accessibility levels have been growing over time due to cheaper and easier medium- and long-distance travel enabled by the car and the plane. However, local accessibility has decreased in several urban areas. This has been the result of low-density, monofunctional urban developments (creating neighborhoods with low local accessibility) in addition to the phenomena of concentration of activities in major regional shopping or retail centers while gradually leaving local communities (decreasing local accessibility in former high-accessibility neighborhoods).

In summary, accessibility losses have been mainly brought about by decreased competitiveness of public transport services (in comparison to car) and by the decreasing availability of local activities (either because it is not economically viable to move activities to low-density development or because it is less economically viable to stay in high-density local neighborhoods than to move to regional shopping centers). In addition, other phenomena, such as traffic congestion, have also decreased accessibility (even car accessibility) while transport infrastructure developments have managed to increase road mobility.

Planning Support

Urban, regional, and national planning. Accessibility and mobility are key factors in the understanding of real and potential flows, interactions, and interdependencies at the urban, regional, and international levels. In terms of economic development, mobility and GDP growth are believed to be directly connected. Current trends argue for a decoupling of GDP and mobility growth and for finding new ways to achieve economic development without increased mobility.

As described above, mobility has been growing, following urbanization and decentralization phenomena of urban areas, making mobility one of the key issues in urban and regional planning but also at the international level. More recently, accessibility

A residential development with a road network emphasizing private car travel over public transport seen near Des Moines, Iowa, in 2011. Such regional car accessibility may be used as grounds for decreasing local public transport service levels.

has also been recognized as a key planning issue, with access being acknowledged as the main planning concern. The primary need of people, and of freight, is to reach desired destinations and activities and not mobility itself. Regardless, the balance between demand and supply of mobility needs is still a key issue in planning. Nevertheless, recent trends have emerged, arguing the need to manage travel by reducing unnecessary travel and making necessary travel more sustainable. These new trends have questioned one of the basic mobility principles—that travel demand is derived.

Planning for mobility versus planning for accessibility. In urban and regional planning, several voices have been raised in favor of a paradigm shift from mobility-based planning to accessibility-based planning. While mobility-based planning holds

mobility and its improvement as its main concern, accessibility-based planning shifts the concern from mobility to accessibility and thus from the ease of movement to the ease to reach desired activities. In practice, while the former planning system favors increasing mobility following the “predict and provide” paradigm (and, in some cases, even provide without predict), planning for accessibility recenters urban and transport planning on the connection of people and activities. Thus, mobility-based planning centers on infrastructure provision and performance while accessibility-based planning looks at travel from a more holistic perspective, considering infrastructure, land use, spatial distribution of opportunities, livable streets, etc., at the same time that it enables comparative analyses of competitiveness of different transport modes. Finally, this paradigm shift results in a shift of focus from the means (infrastructure and its performance) to the ends (fulfillment of people’s expectations).

Transport planners following the traditional “predict and provide” paradigm will say that when they are planning for mobility they are also planning for accessibility: that their aim is to fulfill people’s expectations. This understanding resides on the assumption that all demand is derived from physically dispersed activities and thus, when supplying solutions for demand, accessibility and expectations are also being supplied. However, when planning for mobility and defining demand based on mobility indicators, these are not measuring travel choices available but real travel choices made. Thus, the supply of solutions will favor solving mobility problems (which may increase accessibility, although mainly car and regional accessibility) but not necessarily accessibility problems of all people (especially, car non-users). This means fulfilling peoples’ increased travel requirements instead of fulfilling lifestyle needs. The latter do not include more mobility but refer mainly to the need to reach desired opportunities, if possible, with less travel and with less expenditure. Using only mobility indicators provides planners a limited view on travel needs and on “people’s expectations.”

While traditional transport planning considers mobility to be derived demand, recent research has suggested the existence of other forms of demand, such as induced and latent demand. A basic definition of these concepts describes induced demand

as increased demand resulting of the increased supply (improvement of mobility conditions), and latent demand as potential for increased demand that would be produced by the increased supply. For example, building a new motorway may relieve congestion on main roads, but in the long run, demand may increase more quickly than expected because more people move close to this highway in search of better and cheaper housing with easier access to the city center (induced demand), or because people already living near the new motorway who before never considered commuting to the city center are now able to (latent demand). The latter case is a clear example to how improved infrastructure can generate new travel needs that were not present before and that now become needs and even new rights.

In addition to these alternative forms of demand, recent research has also suggested the existence of undirected and excess travel. Undirected travel is trips made without the purpose to participate in any activity at the destination (or where the activity is a secondary objective), while excess travel is trips with distance, time, or route exceeding the minimum required to access the destination (for example, taking the longer way home to avoid congestion even if it takes the same time).

Conclusion

While both mobility and accessibility are key issues in urban, regional, and international planning, planning should be based on accessibility concerns offering a more holistic perspective on travel, urban development, and people. This will, first and utmost, require dissolving the conceptual mismatch between accessibility and mobility and breaking the traditional approach regarding derived demand.

significant advantages over traditional trip-based models, usually based on a four-step paradigm, in explaining travel behavior and response to policies.

The growing complexity in travel patterns and the need to estimate changes in travel behavior in response to new policies and advanced technology call for a better understanding of such issues as the effects of new information and communication technologies on travel behavior, the effects of land use and growth management on travel behavior, and travelers' response to auto-restraining policies. Understanding such effects, which is essential for an improvement in the design of new policies, is the main motivation behind the development and advancement of activity-based models.

The basic notions of activity-based demand analysis and modeling can be found in the contribution of researchers T. Hägerstrand and F. S. Chapin, who postulate that the activity demand is motivated by basic human desires, such as the desire for survival, social encounters, and ego gratification. Hägerstrand's time geography theory focuses on personal and social constraints when explaining our need for activity participation, while Chapin focuses more on opportunities and choices rather than the constraints.

In activity-based modeling the basic travel unit is a tour defined as the sequence of trip segments that start at home and end at home. Some simplified versions of activity-based models, referred to as tour-based modeling, deal directly with tours without deriving them from the daily activity pattern as done in activity-based models. The explicit modeling of activities and the consequent tours and trips enable a more credible analysis of the responses to policies and of the subsequent effects of policies on traffic and air quality.

The rich spectrum of issues that activity-based models can account for include travel behavior changes in response to activity timing modifications, for example, flexible working hours and opening hours of stores; the impact of various land use policies on shifting activity patterns, such as mixed-use development, that increase walkable access to various activities; and the ability to consider the trade-off between out-of-home and in-home activities. This latter feature is very important in analyzing the effect of technology advancement and Internet services on substituting out-of-home activities requiring travel with in-home activities.

Accident Avoidance Systems

See Automobile Accident Avoidance Systems

Activity-Based Models

Activity-based models are the new generation of travel demand models. Activity-based modeling treats travel as being derived from the demand for personal activities. Travel decisions, therefore, become part of a broader activity scheduling process based on modeling the demand for activities rather than merely trips. These models have

One of the main factors for the improved behavioral realism of activity-based models is their ability to consider the secondary effects of policies. Secondary effects are those adjustments to an activity pattern that are made in response to a primary impact. For example, a transit subsidy may result in a commuter changing the mode of travel for the trip between home and work from drive alone to transit; this is the primary effect of the policy. However, because the person no longer drives to work, it is not possible to stop on the way home to buy groceries. Therefore, when the person now returns home by transit, it is now necessary to take the car and drive to a nearby store. This is the secondary effect.

In such cases, the advantages of the policy may be at least partially offset with the reduction of the work auto trips being replaced by a new shopping auto trip. Activity-based modeling provides a unique insight to such secondary effects.

Another advantage of the activity-based model system is its ability to better consider induced travel and specifically the generation of new trips as a result of transportation improvement as well as trade-offs among different travel behavior decisions. In the four-step model, there are usually no level-of-service variables in the trip generation model, and therefore the model cannot account for generated travel. In the disaggregate activity-based model system, accessibility variables are fed from each level to the level above it and, in this way, changes in level of service by new or improved transportation infrastructure can change not only the mode or destination of travel but also the amount of travel.

The linkages between all the model levels allow for trade-offs between all levels of travel decisions, including between different types of tours. This is a significant improvement over the four-step model in which each trip purpose is analyzed independently from other trip purposes.

Approaches

A variety of research methods have been used to study activity behavior, including duration analysis, limited dependent-variable models, structural equation models, and computational processes models. Different approaches have been used for activity-based models but they usually take one of two main approaches: discrete choice analysis

(DCA) and rule-based process. Based on the DCA approach, scholar Moshe Ben-Akiva and colleagues proposed a practical activity-based, comprehensive, travel-demand modeling framework that captures the mobility, activity, and travel decisions of individuals and households. In addition, a corresponding prototype system of models that can be used for planning and policy analysis was developed by researchers John Bowman and Ben-Akiva. Applications have followed and have been demonstrated for policy analysis by Yoram Shiftan and John Suhrbier.

Some early applications of activity-based models include R. Kitamura and colleagues, who used a dynamic and integrated microsimulation forecasting approach to test transportation demand management (TDM) in the Washington, D.C., area. Other attempts to forecast behavioral changes to transportation policies using an activity-based approach include researcher Patrick Bonnel's in 1995, the STARCHILD model by W. Recker and colleagues in 1986, and the SCHEDULER model by T. Garling and colleagues in 1994.

Today, most advanced metropolitan transportation planning agencies that develop a new travel demand model are developing an activity-based model. Fully developed and applied examples of such models can be found in Portland METRO, the San Francisco County Transportation Authority (SFCTA), the New York Metropolitan Planning Council (NYMTC), the Mid-Ohio Regional Planning Commission (MORPC), and in Tel-Aviv, Israel.

Adopt-a-Highway Program

Adopt-a-Highway has been an important economical and citizen stewardship concept that has saved U.S. states countless dollars and improved the travel environment immeasurably. The idea came about in 1984, when James R. “Bobby” Evans of the Texas Department of Transportation (TxDot) noticed some debris had flown off a passing truck and then onto the road. The citizens’ pickup concept was actually initiated by Billy Black, a public information officer for TxDot, within his Tyler District. Recognizing the fact that the cost of litter pickup was going up 15 to 20 percent a year, the cause for litter pickup needed to be promoted. This would include safety training, the wearing of reflective vests, and other equipment as needed. The Tyler Civitan Club was the first group to “adopt” a highway, cleaning off litter from a stretch along Highway 69. A plaque recognizing their first Adopt-a-Highway efforts was placed on March 9, 1985. There are now thousands of Adopt-a-Highway groups in America and other places, such as Puerto Rico, Canada, New Zealand, and Japan. Every March 9 is now observed as International Adopt-a-Highway Day.

Funding and Program Provisions

Each state, according to its size, budgeting organization categories, and unique concerns, handles the Adopt-a-Highway program a little bit differently. In Arizona, for example, the program is funded by the Intermodal Transportation Division (ITD). The ITD oversees the maintenance of the state’s highway system, with the majority of its funds coming from the Highway User Resource Fund (HURF). The HURF funds the equipment and instructional materials for Adopt-a-Highway through gasoline and fuel use taxes, as well as vehicle license taxes, car registration fees, and other miscellaneous state fees. Other states also put Adopt-a-Highway resources into their respective budgets.

Primary sources of litter in all states are motorists who do not use ashtrays or trash bags in the car but instead toss the garbage onto the highway. Litter may also come from trash containers that have not been properly closed, causing the debris to fly out and land on or beside the highway. Trucks with either unsecured or uncovered loads are at risk of

losing some material to the roadside. And some pedestrians and cyclists passing through on roads other than the interstate highway may toss litter as they go along.

Age and other limitation requirements can also vary from state to state. In some states, adult citizens and minors aged 12 to 17 can volunteer for Adopt-a-Highway, but the minors must be supervised by an adult who is at least 21 and must also submit a youth participation release form to the program. In others states, like California, volunteers can be aged 16 and older, with minors supervised by an adult. The programs must not discriminate based on ethnic origin, race, sex, color or political affiliation. This was put to the test in the state of Missouri when the Ku Klux Klan (KKK), a white supremacist group, tried to get a sign put up acknowledging their work along the highway in Missouri. The State of Missouri refused; the KKK argued that this violated their First Amendment rights to free speech. The case was decided by the U.S. Supreme Court, which ruled in 2005 that the state could not prevent the KKK from participating in the Adopt-a-Highway program.

In California’s Adopt-a-Highway program, handled by the California Department of Transportation (Caltrans), groups have the option not only to adopt multiple sites to maintain but also to assist with vegetation control for environmentally sensitive areas and to plant wildflowers. Caltrans’s rule is that litter removal statewide be done a minimum of six times a year or the length of time it takes for a significant amount of litter to accumulate at the site adopted. If litter adoption is done near a structure like a bridge and there is graffiti, the group or individuals assigned have the option to clean up the graffiti as well. Graffiti removal turnaround time is shorter than litter pickup, and highly visible structures are assigned to be cleaned in less time—almost immediately if the graffiti is considered to be obscene in nature.

For a state the size of California, trash control is a huge enterprise. In 2012 Caltrans spent \$52 million on highway litter removal, including enough trash and litter to fill 10,000 garbage trucks. By mid-2013 Caltrans picked up and hauled away 2,500 cubic yards of trash and sweep nearly 100 tons of debris off state highways, and removed 16,000 square feet of graffiti, with the help of the Adopt-a-Highway program.

An Adopt-a-Highway sign sponsored by a gay and lesbian service organization on Interstate 90 in Minnesota in 2006. In 2005, the U.S. Supreme Court ruled that freedom of speech prevented groups from being selectively banned from the program.

In another very populous state with a big budget, New York, the Adopt-a-Highway program has also been utilized to help keep down state budget expenses. In the late 1980s, the New York State Department of Transportation decided to reassess its priorities when examining the effects of a declining workforce resulting from efforts to save money. With road issues such as maintaining pavements and removing snow and ice, and budget constraints in mind, the Adopt-a-Highway program was initiated. Today, approximately 5,000 miles of New York state highway have been adopted for cleanup.

Special Programs and Recognition

Many states, even those with volunteers to pick up litter in their communities, also utilize inmate or parolee labor to assist them in hauling trash. In order to initiate this program, city or county governments provide manuals with specific instructions on utilizing inmate labor to clean and maintain highways in selected areas of the state. This

special litter program requires inmates to pick up trash, prune trees, perform hand mowing, or cut down brush; in rural areas, they may also clean out culverts. Not every inmate may be entrusted with this task; inmates assigned to these programs are classified as “trustys,” meaning they have not been convicted of a serious crime, which would classify them as a flight risk. In 2009, in Virginia alone, volunteers and inmates contributed their own time to help the state and picked up 26,300 bags of trash along 1,900 miles of highway.

In California, the Caltrans Parolee Program, established in 2009, provides those on parole three months of employment when they leave prison, and it is said to reduce recidivism rates. Since 2009 parolees have removed 50,000 cubic yards of highway litter, an amount equal to 31,000 filled garbage trucks.

The Adopt-a-Highway program saves states many thousands of dollars a year. One of the biggest efforts in the country is in North Carolina, where volunteers have recently saved the state as much as \$4 million a year. With 125,000 volunteers, North Carolina has a very high percentage of participation. These volunteers clean up 12,000 miles of state maintained roads, with 59 local Adopt-a-Highway (AAH) coordinators overseeing their efforts and providing materials. In 2008 citizens picking up trash for the state of Arizona also provided a “statewide labor benefit” totaling \$4 million.

Businesses can assist this antilitter program to advance their entrepreneurial efforts and encourage their employees to be good citizens; a few Internet-based companies specially advertise how they can assist businesses to improve their image by adopting a highway. Businesses have the option of offering to clean up an area of roadside, post a sponsoring sign, and pay someone a service fee to clean it, or they can encourage participation among their employees. In 2009, ConocoPhillips, an energy company based in Houston, Texas, contributed \$70 million to charity, with \$25 million for funding community investment projects like Adopt-a-Highway. With Adopt-a-Highway, Conoco became creative by promoting the Employee Volunteer Grant Program—a national program that enables employees to apply for grants ranging from \$500 to \$3,000 for capital projects or planning projects, with the employees volunteering their time. This special grant program has helped promote environmental responsibility

and awareness among participants who apply for special projects, including those in the Adopt-a-Highway program.

ConocoPhillips and other businesses have strongly encouraged both current employees and retirees to become involved in Adopt-a-Highway as a way to provide a better quality of life in their respective communities. Many transportation departments also present awards to those who participate. In South Carolina, for example, yearly “Pee Dee” awards are handed out for outstanding service by Adopt-a-Highway volunteers or coordinators. With this kind of promotion, the litter pickup becomes a more desirable activity to engage in, and the communities and state both benefit.

Advanced Traveler Information Systems

In recent years, increasing attention has been paid to the development of various applications of Intelligent Transportation Systems (ITS), which are credited with the amelioration of traffic conditions in urban and regional environments. Advanced Traveler Information Systems (ATIS) constitute an important element of ITS by providing potential drivers with information on the network’s current performance both en route and pretrip.

Since information concerning road network conditions and route alternatives is generally either limited or unreliable to the majority of travelers, their choices are often poor, leading to a total increase in distance and/or time traveled. The key principle behind the successful operation of ATIS is that the more informed a driver is (in terms of quantity and quality), the more likely he or she is to avoid forming a false perception and expectation of traffic conditions. In this way, ATIS manages to facilitate travelers’ choices and maximize the utilization of the infrastructure’s capacity. In the long run, ATIS may reduce the need for constructing additional infrastructure due to higher traffic throughput but may also induce additional demand for travel. Regarding society as a whole, given that a considerable number of travelers use ATIS, there will be significant reductions in travel time, fuel consumption, and emissions.

Research on traveler information services sparked in the 1950s and has evolved ever since. The primary objectives for providing travelers with information, however, still remain unchanged, namely, efficient management of traffic, improved traffic safety, and overall enhanced driving operations. Although the first efforts toward the development of ATIS, both in and out of the vehicle (in the form of visual displays informing drivers about upcoming weather conditions) date back to the 1970s, it was not until a decade later that the role of ATIS in the mitigation of the impacts of congestion was stressed. Their primary contribution was to affect en route and pretrip travel choices (departure time, trip destination, route choice, mode choice) and thus maximize the utilization of the available capacity provided by the road network. By the end of the 1980s, the first variable message signs (VMS) were introduced in the United States, informing and advising drivers on possible diversion routes. With emphasis on real-time traffic management, ATIS were further developed and refined during the 1990s as a result of advances in computer and communication technologies.

In the last decade, the philosophy of ATIS has changed significantly so as to encompass a “two-way communication system,” where travelers can interact with the systems, rather than be solely receivers of information. This interaction is facilitated through multilingual visual and auditory interfaces. Moreover, travelers do not only have the

possibility of personalizing the provision of travel information (as they can receive individual routing and travel assistance information based on various criteria—time, distance, cost, etc.), but they themselves also act as transmitters of information.

The ongoing era of development of ATIS is also characterized by a change in what traveler information is and how it is disseminated. Information concerning real-time traffic conditions or routing directions is now enriched, including data on major traveler attractions (theaters, hotels, malls) that travelers might use. For example, there is the possibility for an ATIS to locate and direct a traveler to the nearest restaurant within a radius of 10 minutes' travel time.

In addition, while initial ATIS included VMS and highway advisory radio (HAR), later systems include smartphones, the Internet, in-vehicle motorist services information systems (IMSIS), in-vehicle safety advisory and warning systems (IVSAWS), in-vehicle signing information systems (ISIS), and commercial vehicle operations (CVO) specific functions and in-vehicle dynamic route guidance systems (IVRGS). The latter have the ability to provide routing directions based on prevailing and/or forecast traffic conditions.

Considerations

Due to the fact that ATIS rely on the availability and quality of the data they process, they are accompanied by a series of considerations in regard to their overall functionality and efficiency.

Safety issues associated with the extended use of ATIS, when travelers pay excessive attention to their interaction with the system and eventually become distracted from traffic conditions, are a very important aspect. Recent field experiments showed that travelers respond better to hazard warnings and control their vehicle's direction and speed faster when ATIS are equipped with visual and aural displays.

Market penetration, defined as the proportion of ATIS-equipped vehicles (travelers), is also becoming an important issue, as several studies reveal that there is an optimal number of informed travelers, which, if exceeded, may decrease the overall performance of the network.

Time savings due to the use of ATIS are greatest when a network is saturated (traffic reaches capacity limits), rather than when traffic is lower than

capacity, oversaturated, or incident-free. In the latter cases, route guidance has limited impacts on time savings, thus the trade-off between ATIS cost and perceived benefits may tempt fewer travelers to invest in such systems.

The impacts of ATIS highly depend on how travelers respond to such systems. In this sense compliance with these systems, in regard to the extent travelers follow the provided advice and directions, is directly connected to travelers' confidence in the received information. Should this confidence fail, then the expected benefits in terms of travel time reductions will not be realized. In addition, user friendliness of ATIS is a decisive criterion for travelers to opt for such systems, as they expect a consistent and reliable way of interacting with their in-vehicle devices. Interest is therefore now focused on the overall benefit evaluation of ATIS in order to fully identify the opportunities and risks associated with such technologies. For that reason, various laboratory experiments and field deployments are conducted in that direction, along with the development of mathematical and computer simulation models.

Aerial Tramways

An aerial tramway is a transportation system that uses one or two carriers, or vehicles, suspended from fixed cables while a third cable, called the haulage rope, powered by electricity, provides propulsion. The carriers shuttle back and forth between two end terminals. In jig-back systems, the two carriers always move in opposition to each other. Dual-shuttle tramways use two separate rope loops that allow the carriers to operate independently of each other. Carriers used to move material may be as simple as open buckets, but those used to transport people are enclosed cabins that can accommodate as many as 200 people. Intermediate structures, or towers, support track and haulage cables between terminals. Aerial tramways should not be confused with gondola systems, which use multiple small carriers that circulate along a single cable.

The earliest tramways in the United States were used in mining, but they began to be used to transport people when Americans with more leisure time at their disposal developed an increased interest in skiing and sightseeing in the 1920s. Mining tramways gradually fell into disuse, but aerial tramways began to be constructed in recreational areas. In the late 20th century, city planners realized that the ability of aerial tramways to negotiate natural barriers such as mountains and bodies of water at a relatively low cost could be utilized in urban transit.

Mining Tramways

By the 17th century, primitive forms of the aerial tramway existed in Europe, South America, and Africa, but it was not until the early 19th century when wire rope became available that the potential to use aerial cables to transport freight and

materials was realized. Peter Cooper, an American industrialist and inventor, was among the first to construct tramways for such a purpose. Around 1853, he designed and constructed tramways to carry iron ore to the top of blast furnaces at two sites in New Jersey, but it was the mining boom in the west after the Civil War that brought the aerial tramway into common use.

English inventor Charles Hodgson constructed the first aerial mine tramway in the west in 1871 in the White Pine Mining District of Nevada. The tramway he erected at Treasure Hill, Nevada, transported about 125 tons of ore a day. The tramway constructed in 1872 at the Morning Star Mine about 80 miles south of the White Pine District by Andrew S. Hallidie, wire rope manufacturer and suspension bridge builder, was said to have delivered 10 tons of ore per hour. Hallidie dominated the early period, but competitors were challenging his position by the mid-1880s. By the end of the 19th century, a hundred or more single-rope aerial tramways had been constructed from Juneau, Alaska, to southern Arizona. Mining tramways continued to be constructed as late as the 1950s, but after 1920 low metal prices forced many mines to close. Mines began switching to trucks or conveyor systems, and it was left for recreational use to write the next chapter in the history of aerial tramways.

Tramways in Parks and Resorts

Alexander Bright, a member of the U.S. Olympic Ski Team in 1933, observed the passenger tramways in use in Europe and thought the technology could be used to develop skiing and tourism generally in the White Mountains of New Hampshire. Environmental concerns dictated the choice of Cannon Mountain as the ideal site, as the tramway could be constructed on public land with minimal deforestation. In June 1937, the New Hampshire legislature authorized a \$250,000 bond issue to finance the tramway, and the first passenger aerial tramway in the United States began operation one year later. The tramway carried 163,000 passengers in its first year of operation and more than 6.5 million passengers by the time it was replaced in 1980.

Despite the success of the tramway at Cannon Mountain, chairlifts were cheaper and thus favored in most skiing areas. It was not until the 1960s that aerial trams began to be built with some frequency throughout the United States. The idea of a tramway

in Palm Springs, California, was conceived in 1935, but political jockeying and World War II prevented its construction. Money was raised through private revenue bonds to fund the project, but the Korean War caused more delays. Finally, in 1961, construction began. The tramway was completed in 1963 and designated a historical civil engineering landmark 20 years later. In 2000, renovations made the tramway the world's largest rotating tramway. Delays also hampered the construction of an aerial tramway in Stone Mountain, Georgia. First proposed in the 1950s, it was not until 1962, four years after the state of Georgia bought the land for a park, that the tram began operations. A 25-passenger tram at Heavenly Ski Resort, South Lake Tahoe, California—at that time the largest in the nation—also opened in 1962.

By the end of the 1960s, aerial tramways were operating from Sandia Park, Albuquerque, New Mexico, to Jay Peak Resort, Jay, Vermont. The next decade saw aerial tramways constructed at Pipestem

Resort State Park, West Virginia; Snowbird, Utah; and Gatlinburg, Tennessee. As late as the 1990s, aerial tramways were constructed, including the Mount Roberts Tramway in Juneau, Alaska.

Mass Transit Tramways

In 1976, the first aerial tramway to be used for mass transit was constructed. Originally intended as a temporary measure to solve the problem of lengthy commuter trips with frequent transfer between Manhattan and New York City's Roosevelt Island, the tram proved so popular that it was continued even after a subway station was completed in 1989. The total cost of the system was \$6.25 million; in 2013, the equivalent cost would be more than \$25 million. The tram was closed in 2006 for renovations after passengers were stranded for seven hours on April 18, 2006. Since the tramway reopened in September that same year, the number of daily passengers has increased to an average of 3,750.

In 1999, Portland, Oregon, concluded that an aerial tramway offered the most efficient means of a reliable and rapid transit connection between the Oregon Health and Science University's expanded campus and the waterfront. Construction of the Portland Aerial Tramway began in August 2005; the tram opened to the public on January 27, 2007. The total cost was \$57 million, more than triple the original estimate. Experts predicted that the tram would carry more than 1,500 people daily. The estimate proved modest—1 million passengers rode the tram in its first 10.5 months of operation.

The Future of Aerial Tramways

Economically and environmentally, the increased use of aerial tramways as one solution to the transit problems of urban areas holds great promise. Tram systems can be constructed for only a fraction of the cost of subway lines or light rail. Aerial tramways also have a much more limited environmental footprint than do other modes of mass transit. Trams are energy efficient, and emission rates are low. The systems also negotiate natural barriers without significant topographical changes, and because they are not limited to existing roadways, they cut travel time.

Current technology does not lend itself to the integration of multiple tram systems, and integration into existing transit systems can present challenges as well. Limited capacity and speed mean that the trams cannot equal the capacities of light

New York City's Roosevelt Island aerial tram approaching the Manhattan station in March 2006, the month before a power failure left nearly 70 passengers stranded for seven hours.

rail and bus rapid transit. Additionally, privacy may be a concern when the carriers move over private property. Despite these disadvantages, urban planners in increasing numbers are considering them as an alternative strategy for cities where conventional transit options are limited.

Aeronautical Decision Making

Aeronautical decision making (ADM) is a decision-making system used by pilots and flight crews, with the goal of minimizing accidents and following procedures of maximum safety. The official definition given in the Federal Aviation Administration (FAA) document AC 60-22, which introduces the FAA's guidelines for ADM, is "a systematic approach to the mental process of evaluating a given set of circumstances and determining the best course of action." Most avoidable aircraft accidents are the result not of equipment failure but of pilot error, and the chain of events leading to these accidents is called the error chain or bad judgment chain, which ADM is intended to break. ADM takes the knowledge acquired in primary flight training, especially pertaining to maneuvering in and responding to weather conditions and strong winds, and applies it to the understanding and avoidance of potential hazards. Many of these decisions must be weighed

according to the conditions of the flight, which include not only ambient circumstances like the weather but also the pilot's understanding of his or her own ability and experience, and the design limitations of the aircraft. The best decision in one aircraft is not necessarily the best decision in another aircraft in identical circumstances; likewise, the best decision for one pilot is not necessarily the best decision for another pilot in identical circumstances. Ideally, ADM involves making flight decisions that avoid the circumstances, such as low fuel reserves, necessitating the most difficult decisions. Situational awareness and competent risk management are key.

Remaining aware of and responding to circumstances appropriately may mean avoiding certain situations entirely. Many aviation accidents involve small craft, which do not require pilots of the same experience and skill as pilots of large commercial aircraft, and the most important decision a pilot who is limited in skill or experience can make is to land the aircraft rather than continue in uncertain or dangerous conditions. For instance, the FAA's regulations differentiate between visual flight rules (VFR), which govern flight in weather conditions clear enough for the pilot to see where he is going, and instrument flight rules (IFR), in which the aircraft's instruments provide the necessary information that the naked eye cannot due to weather. Most flights in class A airspace, where jets spend most of their flight time, are IFR flights. Because of the weather conditions that prevail at high altitudes. All such pilots are instrument rated, meaning they have received additional training and experience specific to IFR flights, as well as relevant instruction in meteorology.

The pilot license or commercial pilot license of pilots of smaller craft does not require instrument rating, and one of the most dangerous decisions such a pilot can make is to continue into IFR conditions, when weather has occluded visibility, without being instrument rated. Many aircraft accidents occur when this is unavoidable, which is one reason flights are grounded at times of imminent heavy weather. Further, the transition from VFR to IFR is more stressful and difficult than many non-instrument-rated pilots or even inexperienced instrument-rated pilots may realize, and switching from visual cues to instrument readings frequently disorients the pilot—which is especially dangerous

when the switch is in response to unplanned circumstances. Similarly, the desire to avoid the transition to IFR because one is not instrument rated or is more comfortable with VFR, while also avoiding turning around or terminating the flight, can lead pilots to continue VFR even when visibility conditions have degraded beyond the point of safety. The FAA's rules list specific requirements of visibility and weather conditions for VFR, but a determined pilot may end up "scud running": straining to keep the terrain visible without flying too close to it.

Though some accidents are caused by irresponsible decisions, such as flying too low or attempting aerobatics, a great many accidents occur when the risks are less obvious. The most basic decision is whether to fly at all, and once in the air, whether to continue. The "go or no go" choice is clear when the weather is not: few pilots have trouble deciding to cancel a flight during bad weather. When conditions are more borderline, however, pressures may mount to go ahead with the flight, including the wishes of the passengers, any payment involved in the flight, an appointment or other pressing need to be at the destination by a certain time, and the simple human desire to continue on with the plan in motion. Every flight should be approached with the understanding that it should be undertaken only if the risks are justified by the skill of the pilot and the design limitations of the aircraft. This does not mean flying only when conditions are perfect, but every pilot's plan should include a flexibility and willingness to end a flight early. A cornerstone of ADM is the pilot's evaluation of his or her own attitudes and behaviors, including the way they handle stress and unexpected events, and any attempts to modify these behaviors for the better.

ADM involves both contingency plans and a continuous decision-making cycle. Contingency plans are plans formulated in advance to be implemented in the event of certain conditions, such as weather worsening during the flight or fuel running low. The continuous decision-making cycle is the ongoing process of decision making during the flight, informed both by data prepared before the flight (including the pilot's understanding of his own abilities, the limitations of his license and of the aircraft, weather reports, a prepared flight plan, and information about conditions at the destination) and information gathered during the flight, as a result of changing conditions.

The continuous decision-making cycle calls for the pilot to constantly evaluate flight conditions and be aware of what could go wrong, such as the effects of the weather or the possibility of an engine failure. The FAA advocates the DECIDE model of continuous decision making: detect that a change has occurred, estimate the best response to the change, choose the best outcome, identify the actions necessary to respond to the change, do the chosen actions, evaluate the outcome of the actions taken. The FAA also talks about ADM in terms of the 3-P model: perceive, process, and perform. The pilot perceives the circumstances affecting the flight, processes that information, and considers the impact of those circumstances, before performing the best possible action in response.

Aeronautics

Aeronautics is the study and development of the principles and technology of directed flight. As such, aeronautics encompasses the field of aviation as well as closely related fields, including

ballistics, rocketry and orbital satellite navigation, ballooning, and dirigible technologies. Aeronautics in the contemporary sense is largely concerned with the core physics of aerodynamics and the applied sciences of aerospace engineering, flow dynamics (subsonic and supersonic), flight surface design, and other hard scientific pursuits—as well as the “soft science” aspects of manned flight, such as business and governmental involvement in military, commercial, and private aviation policy, planning, and practices.

Flight Theory Fundamentals

If there is an “Aerodynamics 101,” it can be summed up in four words: weight, lift, drag, and thrust. These are the four key aerodynamic principles specified by Sir George Cayley in his published works of 1809 and 1810. The builder of one of the first human-carrying gliders, Cayley conceived the inter-relationships of these four forces as they applied to the design and function of all flying devices. His work’s fundamental theories were based on aeronautical ideas and works from the giants of philosophy and physical science since ancient times, with prominent names like Aristotle, Archimedes, Leonardo da Vinci, Galileo, Isaac Newton, and Daniel Bernoulli all making their contributions.

Related and integral to these four forces are such design principles as the airfoil, flow separation, aspect ratio, angle of attack, and other aerodynamic fundamentals. Cayley experimented broadly to determine the aerodynamic efficiency of various combinations of such principles, devising and testing contraptions of many types. These ranged from hot-air balloons and dirigibles to triple-decked man-powered flapping-wing planes and included his very important study of whirling-arm gliders and planes, as well as much work devoted to hot-air engines (which were rendered irrelevant by the development of gas-fueled motors).

It was in his work on the whirling-arm glider, in 1804, that Cayley achieved the most viable and useful success in early heavier-than-air flight. Many of his published interpretations of the aeronautical truths he detected as he refined this invention have stood the test of time. Other ideas have been improved upon, some discarded outright. But even today’s sophisticated, computer-aided aircraft design incorporates much of Cayley’s discoveries

about the lift, drag, thrust, and weight components of aerodynamics and their interplay.

Modern Flight

In 20th-century development of flight technology, many streams of applied science fed into aircraft design and deployment: materials science, mechanical engineering, fluid dynamics, and—especially during the last decades of the period—electronic engineering, which in its aviation applications came to be known as “avionics.”

One major theme of aeronautics in this expansive era and continuing into the 21st century has been the stability and reliability of aircraft design. Taken together, these two principles have provided the design basis for the explosive growth of aeronautics into the civilian sector, where flight has become an everyday, background feature of modern life. Inherent stability is a physics and design principle that is prudently crafted into most civil aviation aircraft. Inherent stability means that an aircraft will, by virtue of its fuselage and wing configuration, find and settle into its level, flight-maintaining attitude. This is in contrast to many military combat aircraft, for example, which are purposely designed so as to sacrifice stability in exchange for a far higher degree of maneuverability. Reliability in aeronautics has derived from materials science, engine technology and machining, better maintenance regimes, and the communications infrastructure that literally keeps pilots on course and out of harm’s way.

Another key theme has been the improved application of aeronautic guidance systems, driven in great measure by advances in avionics. Global positioning satellite networks, autopilot refinement, succeeding generations of radar development, celestial navigation, and even some aspects of artificial intelligence computing support have all contributed to the growing sophistication of aeronautic guidance technology that performs progressively better while consuming less energy and less material.

Human Factors

Underpinning all of these technological advances has been the constant, coordinated determination of commercial, military, and government authorities and administrators to organize the progress of aeronautics. This progress has come through the disciplines of better training, steadily expanding education, professional support, mandated policy

principles, regulatory development and monitoring, industrial and institutional reporting regimes, air safety guidance and investigation, intelligent use of enforcement and remediation, and increased focus on smarter planning within and outside the aviation sphere as the world's aeronautical participants grow in number even as they draw closer and become better networked.

Among the major areas of pursuit in aeronautics planning and administration are air safety, training and professional development, airspace organization, and international and regional growth planning. Each of these areas is concerned with the human factor, that is, how the individual—whether a pilot, engineer, researcher, instructor, investigator, security officer, service provider, administrator, architect, mechanic, or contractor—interacts and makes decisions within his or her immediate group, and within his or her work environment. The ongoing evolution of policies covering these interactions and performance metrics is what makes aeronautics as much a field of social organization and administration as it is one of mechanical invention and physical challenge.

Air Safety

Requirements for pilot and support personnel certification has grown into one of the main instruments in reducing air accidents and fatalities. Similarly, mandated aircraft design features and the maintenance, inspection, and overhaul schedules that commercial aviation operators must adhere to have improved the reliability and air safety records across the aeronautics world. Technological advances in air traffic control, radar and other instrument-based guidance and navigation systems, and the inclusion of more accurate airport and runway mapping in aeronautical databases continue to provide better assurance that flights take off and land in a safety-prioritized manner. Each of these advances has required the determination by policy planners that the safety of crew, passengers, and those on the ground must trump any countervailing risk stemming from purely commercial goals.

Many decisions regarding safety-enhancing practices affect the aircraft and its components, along with the standard and emergency procedures of the crew and support staff. However, there are far broader ramifications that involve issues from

airport terminal layout (key to preventing security lapses) to environmental issues (such as bird strikes and volcanic ash dangers) and ground systems redundancy (to forestall air traffic control failure due to electromagnetic surges, for example).

To enact, enable, and enforce the desired level of improvement in aeronautics safety, policy planners have recognized the need for coordinated efforts and cross-agency administration. The two most comprehensive such efforts to date have been the Commercial Aviation Safety Team (CAST) concept in the United States and the European Strategic Safety Initiative (ESSI). Both of these bodies are in turn linked to like organizations in all other parts of the aeronautics world.

CAST plans its Safer Skies Safety Enhancement series of focus areas and improvement bulletins around two main areas of endeavor: manufacturing and air carrier operations. Typical issues might include the proper installation and retrofitting of terrain avoidance warning systems, or upgraded training of flight crews on the use of advanced maneuvers to prevent and recover from hazardous conditions outside the normal flight envelope. ESSI involves more than 150 participating civil and military organizations across Europe that engage in promulgating information and policy on everything from the dramatic, such as parachute instruction, to the seemingly mundane, such as landing gear video monitoring.

Professional Development

Pilot training is the essential building block of professional development in aeronautics, but there are many other components of this field. Aerospace manufacturing, design, and quality control; avionics and telecommunications; airport planning, management, and administration; ground support services contracting; transit capacity planning, intermodal transportation and infrastructure support; air traffic control; security; accident investigation and safety initiatives; education and training; and commercial aviation legal, tax, and competitive issues all come into play.

One regulatory initiative that broadly covers these fields of study, testing, and evaluation from a federal administration standpoint in the United States is the National Aeronautics Research and Development (R&D) Policy, enacted with an accompanying executive order in 2006. This

directive empowered and directed the various cabinet-level agencies of the U.S. government to help shape, guide, evaluate, and police the development of technological innovations and human skills and activities in aeronautics. The ultimate goal of the policy is the “advancement of the nation’s aeronautics enterprise” and leadership “by fostering a vibrant and dynamic aeronautics R&D community that includes government, industry, and academia.” Individual objectives of the policy are to improve aeronautics safety, security, economic power, energy efficiency, and environmental protection, and to achieve “the highest level of scientific, technical, acquisition, and operational education and experience” among the professional aeronautics workforce.

Air Cargo Carriers

The business of transporting cargo by air has almost as long a history as that of commercial passenger aviation, and the early history of air cargo is intertwined with the development of postal air services. Today, air cargo services are provided by a combination of specialist companies (for example, Federal Express) and the cargo divisions of companies that also provide passenger service (for example, Korean Air), transporting over \$6.4 trillion worth of goods annually, accounting by value for about 35 percent of all world trade.

History

The air cargo industry got its start in the period just after World War I, when the availability of surplus military planes (which proved largely unsuitable for passenger service) and trained pilots facilitated the development of air mail delivery services. Subsidies from national governments for mail transport were an important source of income for early freight carriers, and it was also not unusual for the same airlines to transport passengers on day flights and mail and freight on night flights.

In Europe, colonial powers such as Great Britain, France, and the Netherlands embraced air freight as a way to maintain connections with their colonies. In 1923, a study in Great Britain concluded that the best way to meet this goal was to offer subsidies to the many small private companies then offering cargo and mail service between London and other parts of the British Empire. Imperial Airways Ltd. was formed as a result of this merger, and in 1939, it was nationalized and merged with British Airways Ltd., forming the British Overseas Airways Corporation, which later became British Airways. This pattern of many small private air cargo carriers merging into a single national airline was typical in other European countries as well, and many of these airlines remained national entities into the 1980s.

In the United States, the first air cargo flight took place in 1910, and the first dedicated postal service was established in 1918, with intercontinental postal air service beginning in 1924. The Air Commerce Act of 1926 established regulations and standards for air traffic control and pilot training, and classified the role of different airports in a national air transport system. The use of air cargo in the United States grew rapidly, and the American air

Dell computers being loaded onto a China Southern cargo plane in Xiamen, People's Republic of China, in 2009. In 2010 China Southern was the third-largest domestic air cargo carrier in the world, shipping 833,000 tons of freight throughout China.

cargo trade was the largest in the world by the start of World War II. In 1940, United Airlines began operating the first all-cargo service in the United States, and by 1945 several other airlines were also offering commercial air freight services.

In 1929, United Parcel Service (UPS) expanded its package delivery service to include goods transported on private airlines but abandoned the service within a year, due in part to lack of demand caused by the onset of the Great Depression. UPS resumed air deliveries in 1953 but did not acquire its own cargo fleet until the 1980s. DHL, founded by Brian Dalsey, Larry Hillblom, and Robert Lynn, began operation in 1969 on a single route only, offering air courier services from San Francisco, California, to Honolulu, Hawaii; it has since expanded to offer global service and was acquired by Deutsche Post in 2002. In 1971, Federal Express (FedEx) was founded by Fred Smith in Memphis, Tennessee. FedEx began operation in 1973 as an all-cargo airline, offering overnight delivery throughout the United States,

and it is now the world's largest air cargo carrier both domestically and internationally.

The Air Cargo Industry Today

The air cargo industry has enjoyed mostly steady growth since the 1960s, but the pace of growth slowed in the 1980s, and the industry has experienced periods of decline as well. The industry is vulnerable to several outside forces, including general economic conditions in the world, natural disasters, and the price of fuel (in 2010, fuel comprised over one-quarter of operating costs for airlines, according to the International Air Traffic Association). As measured in revenue ton kilograms, global air cargo traffic increased an average of 6.9 percent per year in the 1980s, 6.1 percent per year in the 1990s, and 3.7 percent per year in the 2000s. In 2008 air cargo traffic fell 3.2 percent, and in 2009 it fell another 9.6 percent, marking the first time a decline had been observed in two consecutive years.

In 2011, global air cargo declined about 1 percent, and through the first eight months of 2012, it fell 2 percent. However, even though 2011 was a year of decline overall for the air cargo business, some markets showed growth, including Latin America–Europe (3.8 percent), Europe–North America (3.4 percent), domestic China (2.8 percent), and Middle East–Europe (2.3 percent). Markets with the greatest decline in 2011 were Europe–Asia (minus 7 percent), Asia–North America (minus 5 percent), and intra-Asia (minus 0.9 percent).

Most air cargo (90 to 93 percent) is transported by scheduled air services, with the use of charter services rising during periods of strong growth. Most air cargo is carried by freighter airplanes designed specifically for goods transport rather than passengers; the percentage of air cargo carried by freighters has hovered around 60 percent since 2001. Large freighters, which are more efficient than smaller planes, play an increasing role in the business, carrying 31 percent of air cargo today, as opposed to 22 percent in 2002, and this percentage is projected to increase to 36 percent by 2031.

The leading air cargo companies today include both air cargo specialists and companies that provide both passenger and air cargo service; overall, cargo revenue comprises about 15 percent of total airline revenue. As of 2010, the largest air cargo

carrier in the world was FedEx, carrying 4.985 million freight tons of cargo domestically and 1.965 million internationally, for a total of 6.949 million. UPS Airlines was the second largest, carrying 2.929 million freight tons domestically and 1.580 million internationally, and Korean Air was the third largest, with 1.661 million freight tons internationally and 144,000 domestically. Emirates Airlines was fourth with a total of 1.777 million freight tons, followed by Cathay Pacific Airways (1.579 million). Looking at domestic transport only, after FedEx and UPS, the next three largest carriers were China Southern Airlines (833,000 freight tons), Air China (625,000 freight tons), and China Eastern Airlines (527,000 freight tons). Looking at international transport only, after FedEx, the largest carrier is Emirates Airline (1.777 million freight tons), followed by Korean Air (1.661 million freight tons), UPS Airlines (1.580 million), and Cathay Pacific Airways (1.579 million).

Air Passenger Carriers

The humble beginnings of the air transportation system can be traced to a number of pioneers, pilots, engineers, business leaders, and investors who believed in the future of aviation. They strived to promote the advancement of an organized system to transport people, mail, and freight that would change the future of global transportation. Aviation, from the beginning of powered and controllable flight, offered advantages over existing modes such as shipping and railway. Since the first flight of the Wright Brothers' "Wright Flyer" on December 17, 1903, at the dunes of Kitty Hawk, North Carolina, the public has had an insatiable fascination with flight. The social awareness of the benefits of aircraft as a public utility has been apparent through rapid increases in technology over the last century. Aircraft manufacturers have transitioned from an aircraft that flew only 120 feet in 1903 to the long-range, high-performance jetliners that have become a mainstay of modern society.

Passenger travel by air became a reality for many as early as 1914, with the first scheduled air route between St. Petersburg and Tampa, Florida. Over the next decade, aircraft were developed that could fly higher and faster than their predecessors with a given level of safety, confidence, and regulation, primarily in the carriage of airmail. Even though infrastructure was not fully developed to include a complex system of airways and air traffic control in the pioneering years of air transportation, the need was apparent.

Looming world wars and global conflict during the early and middle 20th century proved the utility of aviation for wartime applications. The need for aircraft to fly greater distances for bombing runs and troop transport during World War I and World War II proved to many that aviation could play a key role in civilian infrastructure. The rapid advancements of technology during war transferred directly into the civilian sector during peacetime, allowing society to benefit from advancements in global transportation. World War II brought about systems such as turbocharged/supercharged engines and pressurization systems, which allowed aircraft to perform at high altitude. This advantage was necessary for newly established air carriers to fly above the weather and ensure passenger comfort.

At the end of World War II in 1945, the early years of the “jet age” had begun, but not without consequence. With the inception of jet aircraft making the world a smaller place and carrying large numbers of passengers, newly developed and highly untested systems had to become a component of industry. For example, the de Havilland Comet was among the earliest jet airliners to enter service; however, the lack of experience in jet aircraft design and construction would prove to be grave. The aircraft was prone to structural failures from a design flaw in the passenger cabin windows. This flaw caused the aircraft to depressurize instantly, causing a high number of fatalities. Another area of concern that had to mature was the air traffic control system. In 1956 a Trans World Airlines Super Constellation and a Douglas DC-7 collided over the Grand Canyon, killing all 117 passengers and crew onboard both aircraft. This particular incident was highly publicized and revealed a need for changes in existing infrastructure that would support more aircraft operating in finite airspace.

As infrastructure started to increase and the public appetite for travel grew, the need for air carriers to have a standardized structure became apparent. Airlines were classified by the type of aircraft they operated, distance traveled, and commodity carried. Airlines were grouped by non-scheduled charter operations, full-service legacy carriers, and regional commuter airline operations. The present air transportation system is a component of many mergers and acquisitions, which are a consistent component of the airline organizations.

Nonscheduled Charter Airlines

During the formative years of transportation by air, the public had limited trust in the reliability and safety of aircraft. Early incidents had plagued the industry with uncertainty that an individual would make it to his or her respective destination safely. This brought about air carriers who operated on an as-needed basis to transport passengers between destinations without the use of a scheduled time slot. This type of air carrier is in operation today and can be regulated under either Part 135 or Part 121 of the Code of Federal Regulations, Federal Aviation Regulations. The regulatory guideline under which each carrier operates is determined by how many passengers and what type of aircraft

each organization utilizes for service. Part 135 is the regulatory policy that provides guidance for small piston, turboprop, and turbojet aircraft carrying less than 30 people, while Part 121 regulates typically large transport category aircraft operating on a nonscheduled basis.

Nonscheduled airlines provide a utility to many passengers who choose to travel on demand or at a nonspecific time. For instance, many sports teams and large interest groups who want to travel together will elect to fly on a nonscheduled charter airline to prevent exposure to the traveling public and to spread the cost over the number of people flying. Nonscheduled air carriers may operate into smaller rural areas where other air carriers may not operate, so consumers have the overall ability to go where they want as long as performance criteria for the aircraft is met. Nonscheduled air carriers are generally smaller than their legacy or regional counterparts; therefore, they make up only a minute percentage of the airline market and are rarely considered when discussing factors that affect industry, such as financial stability and the presence of mergers and acquisitions.

Full-Service Legacy Carriers

A legacy carrier is defined as a type of airline operation that typically offers a higher level of service than smaller regional or commuter-type air carriers. They offer travel over greater distances in large transport category aircraft and include services unique to large operations, such as meals, technology, and full-service amenities. Original legacy carriers include a number of airlines that started service in the 1930s or 1940s. During this era of air carrier development, regulation was imposed and enforced by the Civil Aeronautics Board (CAB), a regulatory agency that became the predecessor of the modern Federal Aviation Administration (FAA). At the infancy of regulatory policy, lawmakers and legislators were very selective in which airlines were approved for operation. Initial startup airlines had to go through an extensive process, which included bidding routes. This process was highly political and limited new entrants to the market. Of all of the startup airlines conceived in this time frame, the “big four” gained an unsurpassed level of popularity, which would impede economic growth but mature the development of a standardized airline market. The big four were

United Airlines, American Airlines, Delta Airlines, and US Airways, all of which are still in operation today. Through this process, maturation of policy, safety, operational objectives, and passenger comfort would provide the necessary framework for the airline infrastructure in existence today.

As time progressed and air carriers became larger, so did the costs associated with travel by air. Fuel costs began to rise and the need for a different economic structure became apparent. During this time, airline ticket prices were regulated by the federal government and started to exceed the economic reach of most passengers. In 1978, the Airline Deregulation Act came into effect, which allowed new entrants easier access to the existing market. With the era of CAB regulation coming to an end and new competition exploding into the business of air transportation, policy and regulatory oversight were immature, as was the understanding of long-term economic effects. Ticket costs were driven to an all-time low, allowing more passengers the ability to travel by air, but this change in cost structure did not come without penalty to both passengers and legacy carriers.

The first of the new entrants in the market was PeoplExpress based in Newark, New Jersey. These airlines offered routes over varied distances at a cost far lower than that of any existing legacy carrier that provided service over the same route. They offered a level of service that was not as comfortable as the larger air carriers but had lower ticket prices. For instance, they charged everyone on the aircraft the same fare, with slight reductions for off-peak operating times. They also charged a fee for checked baggage at a rate of \$3 per bag, which offset some of the reductions in passenger costs. This new idea allowed substantial growth but quickly proved to be problematic to the expected longevity of the startup airline. New air carriers were forced to cease operation because the costs associated with aircraft operation exceeded the revenue gained from carrying more passengers at substantially lower costs than their competitors. For instance, PeoplExpress was in operation only from 1981 to 1987 due to this inability to survive in an evolving market.

To combat the rising cost of jet fuel and other commodities relevant to the operation of large aircraft, a number of methods were used to raise the cost of travel to consumers who purchased tickets in different time frames. For instance, a consumer

A PeoplExpress Boeing 747 in front of a Northwest Orient jet at London Gatwick Airport in June 1983. The early budget carrier PeoplExpress operated only from 1981 to 1987.

who purchased a ticket one day before the flight could pay a substantially higher fare for the same trip than someone who purchased a ticket six months prior.

A documentary by MSNBC, “A Week in the Life of American Airlines,” reported to audiences some of the ways large carriers save money on longer trips. For example, American Airlines removed galleys from aircraft on domestic flights and even olives from salads served on flights. They also used work tools as long as possible before discarding, made parts themselves, and carried only as much fuel as needed to meet the mandated fuel reserves required upon reaching their destination.

These techniques derived through data gathering and evaluation proved to save the airline hundreds of thousands to millions of dollars per year. Unique methods and techniques have been utilized by other air carriers to maximize profits where losses have accrued from the process of deregulation combined with economic recession and are necessary to survive in a somewhat ailing market.

Due to this rapid change in infrastructure and the failure of many startup airlines after deregulation, mergers and acquisitions began to take effect. A merger is defined as the combining of two or more companies. Many of the legacy carriers operating after deregulation began to purchase and acquire the aircraft, routes, and employees of failed airlines. This process is still present in the airline market today. For instance, in 2013, US Airways

merged with American Airlines in order to prevent liquidation due to bankruptcy. This has been a common process for many airlines and allows them the opportunity to restructure under the auspices of a Chapter 11 bankruptcy. Until 2011, American Airlines was the only legacy carrier currently in operation that had not claimed any form of bankruptcy since its inception; however, on November 29, 2011, it was forced to file Chapter 11 bankruptcy and pursue avenues that would carry it through the economic recession.

Low-Cost Carriers

The idea of the low-cost carrier came out of airline deregulation. Air carriers were operating with very minimal profit margins, if any; however, some modern airlines have proven that with the proper business model, longevity may be achieved. Southwest and JetBlue airlines are two examples of low-cost carriers that have had success in the air transportation market. They have both grown substantially since their beginnings; however, they are still not considered to be legacy carriers.

One primary difference that low-cost carriers incorporated into their business models is a reduction in passenger amenities. For instance, Southwest Airlines does not provide first class, business class, or any other passenger separation service that would allow for greatly varied cost variance among consumers on the same flight. This process seems to work very well during time of recessionary economic cycles, because passengers are willing to deal with the opportunity costs of flying at a less expensive rate.

Both Southwest and JetBlue airlines operate with similar profiles; however, Southwest has been established for many years—so long, in fact, that industry analysts and economists have classified a phenomena known as the “Southwest effect.” This refers to Southwest Airlines coming into a market and causing an overall increase in airline travel originating from a community after service to and from that community is established. The airline that improves service or improves cost becomes prolific in establishing a consumer base from that particular domicile for a given time frame. This is an after effect but a component of the need for that sector of society that uses air travel as a mode of transportation. Studies indicate that the majority of low-cost carriers appeal to consumers who travel less

for business and more for pleasure one may assume that business travelers prefer amenities commensurate with the time they spend in an airline seat and care less about the overall cost of the trip.

Commuter and Regional Airlines

Commuter and regional airlines are also a product of the Airline Deregulation Act of 1978. The term refers to air carriers that operate over much shorter distances than their legacy or low-cost counterparts. Passengers can expect minimal passenger comfort, smaller aircraft, and a general lack of amenities, which many express little concern with, given the lower cost associated with travel over a short distance and the advantages over travel by rail or automobile. Commuter airline success follows different models with the only difference between regional carriers being the distance passengers are carried and annual revenue in limited instances. With a general lack of differentiation defined by the Department of Transportation (DOT) between these two carriers, one may assume that operational dynamics are very similar.

Starting in the 1990s, many air carriers began viewing smaller aircraft as a tool to improve efficiency. For instance, a trip from Orlando, Florida, to Atlanta, Georgia (351 nautical miles), with an average of 75 passengers, would be inefficient for a large aircraft capable of carrying 200 passengers. A smaller aircraft carrying fewer passengers could improve the profit along the same route because the majority of seats would be utilized and the overall time difference would be negligible. This is only an example, but such changes were common before the expansion of commuter and regional carriers, causing larger airlines to accrue extreme losses in revenue. The model that commuter and regional air carriers are able to currently operate under is referred to as the “hub-and-spoke” model. This refers to the operation of large aircraft carrying large numbers of people over greater distances to utilize hubs, or centralized facilities, for a large number of incoming flights. The other component of the hub-and-spoke model are the spokes, which refers to smaller airports that are short to moderate distances away from the hub that may be easily serviced by smaller aircraft carrying fewer passengers. This model has proven efficient with legacy and regional carriers and was actually developed by FedEx, a freight organization.

The idea of common airlines operated under the same name, referred to as code sharing, has become common practice between legacy and commuter/regional air carriers, but it has proven to be controversial and to carry a level of liability. In February 2009, a Bombardier Q-400 operated by Colgan Airlines under the name of Continental Connection defined by a code share agreement with Continental Airlines crashed on final approach into Buffalo, New York, killing everyone aboard. After this particular incident, the public lashed out at air carriers. Representatives stated that because the aircraft was operated under the name Continental Airlines, it was assumed that it had the same standards regarding safety, flight duty times, etc., as the larger carrier. This incident led to improvements in regulatory policies governing code share agreements between commuter/regional carriers and legacy carriers.

Conclusion

An important consideration to take into account is how the airline industry has evolved over time. Many air carriers have come and gone; however, the system maintains its integrity through the equilibrium of economic forces and the demand of passengers. These variables help regulate air carriers with regard to route structures, operational considerations, size of aircraft, etc. Regulatory policy and guidelines established by the FAA are evaluated in order to fit the needs of future systems. For instance, the FAA is working toward NextGen technologies, which will significantly increase the efficiency of the airspace system. Off-route airways that utilize Global Positioning System (GPS) technology will allow aircraft to operate more directly from their point of origin to their intended destination. From an economic, political, and social viewpoint, the inception of NextGen technologies will decrease the amount of time aloft and work to increase revenues generated in the entire air transportation industry, thereby allowing it to conform to a level of stability defined by its future operating potential.

Air Pollution, Automobiles

Automobile pollution has threatened urban air quality and climate for decades. Most pollutants are by-products of tailpipe emissions that create respiratory and/or developmental ailments in children and other at-risk populations; carbon dioxide (a by-product of fuel combustion) and other greenhouse gases (GHGs) contribute to global warming. Historically, cities with large vehicle populations have struggled to maintain healthy air environments. Progressively tighter controls on emissions rates and improved vehicle efficiency have significantly reduced such impacts, but rising motorization and the associated vehicle pollution remain serious concerns around the world. In the United States, all vehicles (cars, trucks, buses, and off-road vehicles) produce over half of the nation's smog-forming

volatile organic compounds (VOCs) and nitrogen oxides (NO_x), and roughly three-quarters of its carbon monoxide (CO) emissions. The transportation sector also contributes nearly 30 percent of the nation's GHGs (mostly in the form of carbon dioxide [CO_2]).

Most modern automobiles are propelled by internal combustion engines that consume petroleum-based fuels. Nearly all North American passenger vehicles burn gasoline, but diesel is a popular fuel in Europe and in the trucking industry. Diesel vehicles have made up less than 1 percent of new U.S. light-duty vehicle (LDV) sales (which includes passenger cars, trucks, sport utility vehicles, and vans) since the early 1980s. Both gasoline and diesel vehicles emit by-products following the combustion process that powers the vehicle. These by-products are released from a vehicle's tailpipe and dissipate in the surrounding atmosphere.

Gasoline also emits harmful vapors as it evaporates in vehicle fuel tanks and fuel lines and during refueling. Diesel is much less volatile than gasoline and does not produce a significant amount of evaporative emissions. Modern emissions control systems are able to reduce a large part of all tailpipe and evaporative emissions and are usually required on new vehicles to pass manufacturer emissions standards. (U.S. regulations do not require specific emissions control equipment, so manufacturers are free to use any combination of controls to meet standards.)

Effects

Vehicle emissions can be directly harmful as inhaled, and some also combine with secondary pollutants to produce ground-level ozone (smog) or acid rain. Direct inhalation of CO reduces the blood's ability to carry oxygen to vital organs and may cause significant damage to young children and those with preexisting heart conditions. Particulate matter (PM) also causes direct harm to humans at high concentrations and exposure levels. PM primarily affects the respiratory system, causing asthma, bronchitis, chronic obstructive pulmonary disease, pneumonia, and upper respiratory tract infections. Ozone, NO_x , and VOCs produce similarly damaging effects on human respiratory systems at various concentrations and exposures. Air pollution can also damage agricultural crops and degrade building materials and facades.

Transportation-related pollutants affect drivers, cyclists, pedestrians, and other road users, as well as those living near major roadways and freight railways. Roughly 11 percent of U.S. households live within 100 meters of a four-lane highway and so are exposed to pollution's health effects. Populations living near these areas may be economically disadvantaged or minority groups, who are often disproportionately exposed to areas of poorest air quality.

Emissions Regulations

Air quality became a major concern around the mid-20th century, as more automobiles packed the roadways and cities grew while accommodating the new mode. In the United States, the 1970 Clean Air Act set standards for automobile emissions rates and developing acceptable urban toxin levels for key health-impacting pollutants. These efforts are considered mostly successful to date: nearly all of the United States now enjoys the original air quality targets for CO, NO_x , and sulfur dioxide (SO_2).

The Environmental Protection Agency (EPA) maintains that modern light-duty vehicles and heavy trucks are up to 95 percent cleaner than models manufactured before emissions regulations took effect, and over 26,000 premature deaths, 19,000 hospitalizations, and 3.2 million lost work-days have been avoided as a result of actions taken to meet Clean Air Act requirements. Between 1990 and 2008, total U.S. VOC, CO, and SO_2 emissions were reduced 31, 46, and 51 percent, respectively. Thanks to fuel regulations, ambient air concentrations of lead, which at high concentrations can cause mental disorders in children, have also fallen dramatically: 92 percent since 1980.

Most developed countries set vehicle emissions standards that manufacturers must meet or pay penalty taxes. Some U.S. states also require periodic emissions testing to ensure vehicles meet current standards. The EPA standards allow vehicles to emit up to a maximum amount of emissions per mile, based on vehicle type, and at different levels of vehicle mileage. The EPA specifies maximum emissions limits for NO_x , PM, CO, formaldehyde (HCHO), and nonmethane organic gases (NMOG), at or below 50,000 miles (of total driving distance for the vehicle), and again at or below 120,000 miles. Standards are separated into "bins" so that certain vehicle types (like heavy sport utility vehicles

[SUVs], for instance) reside within a specific range of realistic emissions levels.

Air quality improvements have been achieved through progressive emissions regulations on new vehicles, which prompted manufacturers to improve engine design and introduce new emissions control technologies such as secondary air injection, exhaust gas recirculation systems, and catalytic converters. Catalytic converters were introduced in the mid-1970s to reduce hydrocarbon and carbon monoxide emissions, and they indirectly spurred a transition to unleaded gasoline. Up until this time, gasoline contained portions of a lead-based compound (tetraethyllead) to reduce valve wear and uncontrolled combustion (engine “knocking” or “pinging”) and improve compression ratios (for increased efficiency), but the lead component effectively inactivated the catalytic converter. Tetraethyllead’s benefits were reproduced by other, less harmful petrochemical additives, and the compound has been completely phased out of gasoline mixtures in most countries. Catalytic converters therefore led to dramatic reductions in ambient lead concentrations alongside reductions in hydrocarbons (HCs) and CO. Advances in onboard computer technologies and oxygen sensors in the early 1980s helped further reduce NO_x emissions by optimizing catalytic converter efficiency, alongside exhaust gas recirculation systems that redirect inert exhaust gas back to the cylinders.

Exhaust emissions include those emitted from the vehicle’s tailpipe during idling and driving as well as from engine starts. Emissions control equipment operates best once the engine has warmed up, leading to greater emissions during engine starting cycles. These emissions, distinct from typical running emissions with a warm engine, are referred to as “cold start emissions.” Though most CO and NO_x emissions are produced from running exhaust emissions, around 20 percent may be attributed to the cold start process. This share depends not only on the ambient air temperature but also on the amount of running emissions, which are variable among vehicles, and especially under different operating conditions—mainly running speed and engine load from hill climbing or descent. Exhaust emission (and fuel use) rates vary significantly by speed and acceleration profiles.

The EPA provides the MOVES (Motor Vehicle Emissions Simulator) tool to help model emission

rates for vehicle types under various use and environmental settings. PM_{2.5} emissions vary with speed and air temperature and can be estimated with MOVES.

Volatile Organic Compounds

VOCs are released through evaporative processes, even in some vehicles with evaporative emissions controls. Evaporative emissions are especially likely on hot days under a few different parts of a vehicle’s use cycle. For example, “running loss” emissions occur while the engine is hot, and “hot soak” emissions occur while the engine is still hot after a trip. VOCs may also be released during refueling, when the fuel tank is exposed to air, or even while the vehicle is parked and the engine is cool on high-temperature days. VOCs are mostly emitted during cold start and running, but a significant portion also includes evaporative losses during and after vehicle use, as well as while parked. The MOVES tool can estimate VOC venting as it varies across times of day and ambient temperatures and as typical gasoline passenger cars end their trips and are parked.

Alternative Automotive Fuels

Though gasoline and diesel fuels power the great majority of vehicles on the road, other fuels and propulsion systems are growing in popularity. Natural gas, in either a highly compressed (CNG) or liquefied (LNG) form is used in some commercial truck and bus fleets in the United States, thanks to its plentiful availability and competitive price. Natural gas is an attractive alternative to gasoline and diesel, due to its often cheaper cost and fewer pollutants produced at the tailpipe. Relative to gasoline vehicles, natural gas vehicles (NGVs) may reduce life cycle GHGs by around 6 to 11 percent. CNG passenger vehicles may reduce VOC emissions by 72 percent and NO_x emissions by 12 to 19 percent, relative to comparable gasoline vehicles. Despite these benefits, few personal passenger vehicles burn natural gas fuels, and the number of natural gas fueling stations (either CNG or LNG) is much more limited than those offering gasoline and diesel fuels.

In addition to pollutants that negatively impact health, focus is also placed on reducing GHG emissions that drive climate change. Automobiles are major contributors to carbon dioxide emissions, a

primary GHG; they also produce some methane, another GHG. Carbon dioxide emissions are primarily a function of vehicle miles traveled and vehicle efficiency. Efficiency depends on fuel economy (determined by engine efficiency and weight) as well as driving behavior. Rapid acceleration and braking lead to increased fuel use and therefore to higher CO₂ emissions. Even with smooth driving, vehicles are most efficient at cruising speeds, between 30 and 60 miles per hour. In congested conditions, vehicles have the highest emission rates, but efficiency decreases at higher speeds as vehicles exert increasingly great amounts of energy to overcome large drag forces. Other automobile pollutants also follow this general trend, which adds motivation to reduce roadway congestion.

Electric and hybrid electric vehicles (HEVs) offer further ways to reduce tailpipe emissions, to as much as zero in the case of a fully battery electric vehicle (BEV) or hydrogen fuel cell vehicles. While electric vehicles improve local air quality, their use may simply shift pollution to upstream point sources (power plants), and generating electricity from coal plants to run BEVs may produce more total emissions than would HEVs that uses gasoline to power an electric motor. As new HEV and BEV models emerge around the world, consumers have more opportunities to pollute less per mile driven.

Even with the introduction of promising new automobile technologies (and greater use of renewable feedstocks for electric vehicle power), pollution remains a concern. Fleet turnovers are slow and gradual, and many new car owners are anticipated in China's and India's big cities as well as elsewhere. North America, Europe, and many other developed regions have managed to significantly reduce automobile emissions but still face challenges as urban growth continues. Achieving and maintaining clean air and more efficient vehicles around the world will dramatically improve health, reduce degradation of the built environment, and avoid negative impacts to agriculture and the natural environment.

Air Pollution/Air Quality

The transport sector is one of the main contributors to local and regional air pollution and has direct impacts on human and environmental health that are particularly pronounced in urban areas. This article discusses the most common air pollutants emitted by surface transportation and the main factors that influence their concentration in ambient air. Major trends in these emissions are highlighted for the United States and Europe, their human health impacts are described, and U.S. and European Union (EU) air quality regulations are briefly introduced.

Transportation Sources

In addition to carbon dioxide (CO₂), a major greenhouse gas, the combustion of fossil fuels in surface transportation produces the following:

- Carbon monoxide (CO)
- Nitrous oxides (NO_x), consisting of nitrogen dioxide (NO₂) and nitrogen monoxide (NO), which under solar irradiation and with ambient oxygen form ozone (O₃) as a secondary pollutant
- Sulfur dioxide (SO₂), a major contributor to acid rain
- Volatile organic compounds (VOCs), another contributor to O₃ formation
- Particulate matter (PM), which is composed of different solid and liquid substances collectively defined by their very small particle diameter of below either 10 (PM₁₀) or 2.5 μm (PM_{2.5}; 1 μm or micrometer is 1 millionth of a meter)

PM is also created through abrasion of brakes, clutches, tires, and road surface materials, and it is often resuspended into the air column through the turbulence from passing vehicles once it has settled on the ground. Because part of the total PM found in the air comes from sources other than transport, these resuspended particles may originate from industry, home heating emissions, dust from construction sites, or biological matter such as fungal spores or pollen. VOC emissions further arise through evaporative losses from carburetors, fuel tanks, and at filling stations. By 2012, the sale of leaded gasoline had been phased out in most if not

all countries globally, but lead from other sources can still be detected as an air pollutant.

The nature and quality of the fuel burned has an important impact on associated air pollution effects. Diesel fuel—used in virtually all heavy goods vehicles, nonelectric train engines, many buses, light trucks, and passenger cars—creates significantly higher PM emissions than gasoline. Biodiesel (from vegetable or animal matter) generally results in lower CO, PM, and hydrocarbon but higher NO_x emissions than conventional diesel. Gasoline has a significantly higher content of VOCs than diesel. The mixture of oil and gasoline required by the two-stroke engines of small two- or three-wheelers (for example, mopeds, scooters, motor rickshaws) results in much higher emissions of smoke, CO, VOCs, and PM per unit of fuel burned than pure gasoline.

The fuel used in shipping can contain up to 3,500 times more sulfur than is permitted for fuels used in land-based transportation: 10 parts per million or 0.001 percent allowed in liquid fuels for land transport in the European Union and California, 15ppm in the rest of the United States versus 3.5 percent permitted for international shipping by the International Maritime Organization. Compressed natural gas (increasingly used in urban buses, for example) burns cleaner than other fossil fuels, producing lower CO₂, CO, and hydrocarbon but higher NO_x emissions. Hydrogen has no carbon content and thus hydrogen engines do not emit carbon compounds, though depending on the energy source, they may be created when hydrogen fuel is generated.

Other processes associated with transportation also play a role in air pollution. Refining liquid fuels from crude oil results in significant local emissions of CO, NO_x, hydrocarbons, particulate matter, and sulfur compounds, although air quality regulations in the United States and the EU require refinery gas to be of a certain quality before its release. Even the spray painting of vehicle body parts in local workshops can release notable amounts of VOCs into their neighborhoods.

Weather and topography further influence local and regional levels of air pollution from transport activities. In high-pressure weather systems, temperatures in the air column can increase with distance from the ground. In combination with low wind speeds, such inversions can trap pollutants

near the earth's surface, where they accumulate. So-called smog is a consequence of such conditions and can lead to visible "pollution ceilings" above urban areas. The problem can be exacerbated by local topography, if a basin location or nearby mountain ranges prevent the dispersion of air pollutants. Smog was originally associated with coal and wood smoke from industry, power generation, and domestic heating rather than with transport emissions (smog = smoke + fog). The more recent version, photochemical smog, contains compounds created through chemical reactions between NO_x , hydrocarbon compounds (part of the group of VOCs mentioned above), and ambient oxygen. Elevated ground ozone levels are one result of these reactions, which are facilitated by solar irradiation. Transport emissions are the main contributors to photochemical smog, which is primarily observed over large urban areas.

High wind speeds can help disperse air pollutants more quickly away from their source, reducing their local concentrations. However, depending on prevailing wind directions, air quality can in turn be affected in areas that are quite remote from the original source of the pollutants or their precursors. A prominent example can be found in the U.S. Yosemite National Park, which in summer frequently experiences strongly elevated ozone levels as a consequence of emissions created in the San Francisco Bay area, about 200 kilometers away. This phenomenon affects both visitors and plant life. Comparable and longer-range transport has been shown for NO_x and particulate matter, with associated consequences for the health of people and ecosystems.

Trends

In the United States and Europe in 2010, of five major air pollutants (CO , NO_x , SO_2 , $\text{PM}_{2.5}$, SO_2 , and VOCs), transport produces more NO_x emissions than all other sectors (commercial, institutional, and household fuel combustion, and the energy sector and industrial processes) and ranks second or third on other pollutants, excluding SO_2 , where the main share of emissions in both regions in 2010 is created by coal burning in the energy sector. The variations between these two world regions have at least three reasons. First, different transport modes contribute differently to the totals: in Europe, international and domestic shipping

plays a much larger role than in the United States, for example, and this significantly increases the transport sector's relative contribution to overall sulfur dioxide emissions (fourth column). Second, the relative contribution of nontransport sources depends on the respective fuel mixes (coal, oil, gas, nuclear, renewables), the types of industry, and the overall volume of their emissions relative to those from transport. Third, the compilation of such statistics relies on a combination of measured and modeled data from secondary sources, the quality of which may vary.

The trend in emissions of the same pollutants from transport activities in relation to 1990 as the base year also showed decreases relative to their 1990 levels, though not at the same rate. Taking into account the methodological change in measuring SO_2 emission in the United States, sulfur oxides emissions from land-based transport have reduced substantially in both Europe and North America due to fuel-quality regulations. That situation is different in other parts of the world, though, where up to 300 times higher sulfur levels are still permitted in diesel fuels for land-based transport. The widespread introduction of catalytic converters has greatly contributed to reducing CO and VOC emissions. Emissions of these three groups of substances have decreased much more rapidly than $\text{PM}_{2.5}$ and NO_x —though none have disappeared completely.

$\text{PM}_{2.5}$ arises in the transport sector from sources other than the engine and is harder to eliminate from tailpipe gases than larger particles, for example. Nitrous oxides are created in the engine from nitrogen present in the air needed for combustion and thus cannot directly be addressed through fuel quality. In addition, the use of alternative fuels sometimes results in higher NO_x emissions than from conventional diesel or gasoline.

Quantifications of air pollution are very sensitive to the chosen methodologies, which may vary between regions and over time. This should be borne in mind in their examination and comparison, though their importance and usefulness are undisputed.

The trends described above are averaged over large areas and while it is generally true that air pollution from transport there has decreased over the last decades, the nature of this development is not the same everywhere. Local and regional transport

A line of cars passes through an area of severe air pollution from heavy industry on Clark Avenue in Cleveland, Ohio, in July 1973. The Clean Air Act of 1970 and its amendments helped lead to an improvement in average air quality across the United States. Between 1990 and 2008, total U.S. volatile organic compounds, carbon monoxide, and sulfur dioxide emissions were reduced 31, 46, and 51 percent, respectively. Fuel regulations have also led to a 92 percent decrease in ambient air concentrations of lead since 1980.

emission trends may be either better or worse, depending on, for instance, the specific development of transport volumes and fleet composition.

Health Impacts

Experts now generally agree that there are no threshold effects for the classic air pollutants from the transport sector: carbon monoxide, nitrogen dioxide, particles, ozone, and sulfur dioxide. In other words, it has not been possible to show any level at which these substances do not have a negative impact on human health, though the nature and magnitude of this impact varies with the concentrations people are exposed to and with the length of that exposure. In general, the increased mortality linked to chronic exposure to air pollution is thought to be greater than the mortality risk

linked to acute exposure. Studies on the number of premature deaths caused by emissions from the transport sector in Europe and the United States generally estimate figures on the order of tens of thousands. Connections between chronic exposure and increased morbidity (for example, cardio-respiratory problems, pulmonary function) have also been found in both children and adults.

Specific health impacts from transport include the effects of carbon monoxide, nitrogen dioxide, particulate matter, sulfur dioxide, volatile organic compounds, and ozone. Carbon monoxide (CO) binds to hemoglobin with a 200-times-greater affinity than oxygen to form carboxyhemoglobin (COHb), decreasing the delivery of oxygen to the cells. Increases in COHb create cardiac stress and can exacerbate or bring on symptoms of angina

pectoris. While legal limits for ambient CO are now rarely exceeded in developed countries, prolonged exposure can still result in personal COHb levels becoming elevated.

Elevated levels of nitrogen dioxide (NO₂) are associated with impaired lung function in asthmatics and possibly also with higher sensitivity to allergens.

Particulate matter (PM) can have different physiological and toxicological effects, depending on composition and particle size. The smaller the particles, the farther they can penetrate into the human body and the worse are the health effects associated with them. PM₁₀ can cause irritation to eyes, nose, and bronchi, while smaller particles in the PM_{2.5} fraction can penetrate as deeply as the lungs's alveoli, from where they may reach the blood. Exposure to PM is associated with acute respiratory problems, prolonged respiratory illness, cardiovascular diseases, and exacerbation of existing pathologies (such as asthma). Chronic exposure to PM is likely to shorten life expectancy.

Sulfur dioxide (SO₂) in high concentrations causes irritation of the upper respiratory tract and other membranes in eyes and nose. It can worsen the symptoms of asthma and is associated with elevated numbers of hospital admissions (a common health effect marker in epidemiological studies) and even increased mortality due to pulmonary and cardiovascular diseases.

The term *volatile organic compounds* (VOCs) describes a group of substances many of which are toxic or known carcinogens, such as 1,3-butadiene, benzene, and polyaromatic hydrocarbons.

Human exposure to elevated levels of ozone (O₃), a secondary pollutant from the transport sector, results in reduced lung functions in both asthmatics and non-asthmatic individuals, though health effects seem to be more severe in those already suffering from chronic respiratory problems. While symptoms associated with short-term exposure to elevated O₃ levels (such as coughing and shortness of breath) do not normally persist, long-term exposure might cause more severe and lasting damage.

Regulations

Under the Clean Air Act (CAA, 1990) the U.S. Environmental Protection Agency must set National Ambient Air Quality Standards (NAAQS) for six common air pollutants: PM, ground-level O₃, CO,

SO_x, NO_x, and lead. The CAA had a major impact on air quality in the United States.

In the member states of the European Union, the main driver for a continuous assessment of urban air quality and its improvement in connection with road transport is the EU's Directive on Ambient Air Quality and Cleaner Air from 2008. It defines limit values for CO, PM₁₀, PM_{2.5}, SO₂, NO₂, NO_x, benzene, and lead. The translation of this directive into national legislation was mandatory for EU member states. It has resulted in an obligation for the relevant public bodies to monitor or model immissions of these substances and take action if legal limits are exceeded. Many European cities are failing to meet the current limits for PM₁₀, PM_{2.5} and NO₂.

In most cases, air quality standards represent a compromise between what is theoretically required from a public health or environmental point of view and what is deemed politically feasible or desirable. The same applies to the way air quality is assessed, that is, the density and siting of monitoring stations.

Air Taxis

Air taxi operations are on-demand charter flights, especially passenger flights but including cargo aircraft. They are principally a phenomenon of the 21st century, with most air taxi companies founded during or after the post-9/11 development of the Small Aircraft Transportation System (SATS), a joint project between the Federal Aviation Administration (FAA) and the National Aeronautics and Space Administration (NASA). One of the advantages of air taxi services is their use of general aviation airports, of which there are approximately 10,000 throughout the country, compared to the 330 airports served by commercial airlines.

When security measures were increased following the September 11, 2001, terrorist attacks, the aviation industry and its patrons suffered from significant increases in the time passengers spent in the airport prior to their flight. The SATS project studied general aviation—all forms of civil aviation other than the scheduled air services of the airlines—as a remedy to the problem. The possibility of strengthening general aviation, which is served by a significantly larger number of airports in the United States, had been discussed in the industry for decades, and the SATS name came from a 1997 NASA presentation. SATS focuses on addressing travel needs through the use of small aircraft rather than large jet airliners used as mass transit. The main concern was safety issues: weather has a greater effect on small aircraft, whose pilots may be less experienced than pilots of commercial jet airliners, and the safety record for general aviation overall is poorer than that of scheduled air service. Increasing the volume of general aviation traffic without addressing this would be problematic.

The SATS work, conducted from 2001 to 2006, fell into four broad areas: high-volume operations without control towers, improved landing systems usable in most weather conditions, higher capacity air traffic control systems usable in general aviation, and improvements in pilot abilities.

Eclipse Aviation and DayJet

The end of the SATS project coincided with the official introduction, after years of development, of the Eclipse 500 from Eclipse Aviation, the first of a new class of aircraft called the very light jet (VLJ). The VLJ is a small jet aircraft for a single pilot with 4–8

passengers, and it filled the niche SATS sought to fill. While some VLJs are used for personal use, they have provided the backbone of the air taxi industry, with faster speeds than older classes of small aircraft and significantly lower operating costs than larger jets, as well as the ability to take off and land on much shorter runways (as short as 3,000 feet).

The term *very light jet* has been somewhat deprecated because of the bankruptcy of Eclipse Aviation, and the failure of DayJet, the pioneering air taxi service that used Eclipse 500s. DayJet, based in Florida, began operations in October 2007 with a fleet of 12 Eclipse 500s and a series of orders totaling 1,400 of the manufacturer's 2,500 orders. Beyond the use of smaller jet aircraft, the key to DayJet's service and the air taxi industry as a whole was its on-demand nature. Rather than schedule flights and layovers according to complicated algorithms and then seek passengers to fill them, as the scheduled air service industry does, air taxis take a small group of passengers to their destination on demand.

Instead of expanding as planned, DayJet was quickly forced to scale back its fleet because of prevailing economic conditions, and it ceased operations on September 19, 2008, as the worldwide financial crisis crested. DayJet and Eclipse's fortunes were entangled. Eclipse's lack of funding had halted the production of the Eclipse 500 a few months before the DayJet closure, and Eclipse became the broker selling off DayJet's fleet, while itself entering into bankruptcy in November 2008. Its assets were acquired in August 2009 by Eclipse Aerospace, a company formed expressly for that purpose.

The Industry

The collapse of DayJet was prominent enough that many believed the air taxi industry had died with it, but in truth the industry was still getting started. However, two other companies, Pogo and SatsAir, have similarly gone out of business due to insufficient capital. Nevertheless, by 2013 some two dozen companies offered air taxi service in the United States, in addition to Canadian firms. Some had fleets with as few as five aircraft, and many served only specific regions (much as taxicab companies do on the ground).

The term *very light jet* is sometimes still used in the industry and by the FAA, but in dealings with the public, the term *personal jet* tends to be more common, though describing the same types of

aircraft. Cessna's Citation Mustang with six seats, along with the Embraer Phenom 100, is one of the most successful VLJs now that the Eclipse 500 is out of production, although Eclipse aircraft continue to be used as well. The Phenom 100 (used by JetSuite, founded in 2009 in Orange County, California) is the only common VLJ to come equipped with a fully enclosed lavatory as a standard feature. Other VLJs offer the option of sacrificing a passenger seat in favor of a lavatory enclosed by a curtain. Air taxi service typically revolves around hour-long flights, for which an on-board lavatory is not considered crucial.

As with any other transit service, one of the keys to a successful air taxi business is reducing the number of empty legs—flights without passengers—necessitated by needing to move the aircraft to another airport to pick up passengers. Ideally, roughly equal numbers of passengers travel from Point A to Point B as from Point B to Point A, though more complicated arrangements are equally acceptable, so long as aircraft are kept in use and the number of empty or underfilled legs is kept low. This is where much of the challenge of the business model lies. With a larger fleet, the significance of any one empty leg is lower, provided the fleet as a whole is kept active and full; however, an empty leg is a greater burden for a company offering only a few flights. Building up a base of repeat customers can also be important.

Some air taxi providers have also benefited from partnerships with commercial airlines. JetSuite, for instance, partnered with Singapore Airlines to provide service for passengers to and from major metropolitan airports. While many major airlines partner with smaller regional carriers for service to smaller airports, the advantage JetSuite offers to Singapore Airlines is service to general aviation airports that have no commercial airline service. JetSuite, in turn, benefits from introducing airline customers to its service. (JetSuite has also led the industry in social media outreach, notably a \$1 airfare promotion that brought significant attention to its Facebook and other social media pages.)

Air Traffic Control

No mode of public transportation has a greater emphasis on safety than the aviation industry. From manufacturing to maintenance requirements, every phase of air travel is closely scrutinized to ensure the safest environment for the air traveler. This same mind-set extends into the role of the professional air traffic controllers who must move the vast number of daily flights and the passengers aboard them. These efforts have resulted in the development of the safest mode of travel available—commercial flight. The thousands of daily flights that involve private general aviation aircraft also factor into this mix.

So how does one constantly mix the largest of jumbo jet aircraft with the smallest of privately owned aircraft and still maintain the level of safety demanded by the flying public? The Federal Aviation Administration (FAA) has structured the National Airspace System (NAS) in a manner to ensure the separation of aircraft from other aircraft that share the crowded skies. Through years of aviation accident investigations and incident reports, the FAA has also constantly developed and revised specific procedures and phraseology that must be adhered to by all air traffic controllers. These procedures and specific ways of communicating with the aircraft, and with other controllers, ensure that the controllers maintain a safe, orderly, and expeditious flow of air traffic.

Preparing for Safety

To be able to comprehend the methods of separating aircraft, it is necessary to be able to visualize airspace as a three-dimensional block when looking at the flat surface of a radar scope. Air traffic controllers are trained to form a mental picture of the constantly changing traffic situations taking place within their airspace of responsibility. They ensure that the traffic is kept apart by applying rules of separation that are broken down into miles, altitudes, airspeeds, and times. Remembering that three-dimensional picture, one must understand that all the aircraft that a particular controller is working are being separated vertically, laterally, longitudinally, or visually. To further complicate the air traffic picture, factor in the differences in aircraft performance capabilities, such as airspeed, climb rate, and wake turbulence situations caused by mixing larger aircraft with smaller ones.

Every procedure and every phrase to be spoken, and how it is to be spoken, is provided by the FAA in great detail in one publication. The *FAA*

Handbook 7110.65 is the procedural bible for air traffic control operations, procedures, and phraseology. The FAA uses this publication to mold every air traffic controller and to guide them in their daily operations for the rest of their careers. This ensures uniformity and a mutual understanding of all of the safety requirements and how they are to be maintained.

Air traffic controllers begin early with the training process. The vast majority of controllers are graduates of Air Traffic-Collegiate Training Initiative (AT-CTI) schools. These are colleges and universities selected by the FAA to provide training to undergraduate students attending these institutions. The training includes classroom lectures, laboratory simulations, and assessments of the students' performance. During their training, the controllers are exposed to as many types of emergencies as possible through the use of simulation. This helps in the development of a fine-tuned response that is mostly human reflex. The students are taught that the first operational priority of air

Air traffic controllers at work in a new 11-story control tower at Pope Field, North Carolina, in June 2013. Air traffic controllers must keep aircraft that are at the same altitude, or close to it, at a lateral distance of either 3 or 5 miles from each other, depending on their distance from the radar. If an aircraft is over 40 nautical miles from the radar, the 5-mile lateral separation is required because radar becomes less accurate the farther an object is from the antenna.

traffic control is to separate aircraft and to issue safety alerts. A safety alert is defined as an aircraft coming within close proximity of basically anything that will make it come to a sudden stop, such as an obstruction, terrain, or another aircraft.

Safety Measures in a Radar Environment

Over the years, the FAA has devised a strong and proven system of separating aircraft. Presented here is a brief overview, or explanation, of how that system actually works. The goal of any separation system is to keep the targets separated. This is not rocket science. The first requirement is to establish a minimum distance that must be maintained to separate aircraft. This is called the separation minima. It is quite a logical system. Remember, as previously stated, all aircraft are being separated vertically, laterally, longitudinally, or visually. Approach control works the traffic in the air around the airport and usually out to a distance of approximately 60 miles with varying upper-level ceilings, depending on the airspace structure allocated to them.

For aircraft at the same altitude or less than 1,000 feet apart vertically, the minima is either 3 miles or 5 miles. The exact distance required between the aircraft is determined by how far the aircraft are from the radar antenna. Radar is inherently more inaccurate the farther an object is from the antenna. To allow for this “slop” within the system, the FAA has established a range of 40 nautical miles as the changeover point. If the aircraft to be separated are within 40 miles of the antenna, the controller must maintain 3 miles between the targets. If the aircraft are 40 or more miles from the antenna, the controller must maintain 5 miles between the targets. This is called lateral separation because the range is the lateral distance between the aircraft. Remember, they are at the same altitude.

Most air travelers have landed at a large, high-volume airport with parallel runways and, looking out the window, have seen other aircraft landing at the same airport that were less than 3 miles away. So, how can this be legal after reading and understanding the rules given above for lateral separation? It is really quite simple. When parallel runways are located more than 2,500 feet apart, they are considered to be a single runway and simultaneous operations may be conducted without regard for the lateral separation requirement. This operation is perfectly safe and allows the controllers to

expedite the arriving traffic. Imagine how much of a delay there would be if 3 miles had to be maintained between each arriving aircraft at an airport with the traffic volume of Atlanta or Dallas/Ft. Worth airports.

For aircraft that are receiving vectors, or turns, within the arrival traffic pattern to position them for landing on the runways at an airport, vertical separation is also used. When controllers are using vertical separation, they are keeping the aircraft separated by 1,000 feet vertically. Controllers ensure that all arriving aircraft receive the local altimeter setting, or barometric sea-level pressure, as they arrive into the airspace. Therefore, all aircraft under one approach controller’s jurisdiction will be using the same altimeter setting, ensuring a uniform, consistent measurement of distance between each aircraft. Having all aircraft use the local altimeter setting ensures that the vertical distance between aircraft is accurate and the controller is using the aircraft’s exact altitude, since altitude is measured by pressure differential, or variation, from sea level. All aircraft below 18,000 feet operate on local altimeter settings.

All these rules and measurements work fine as long as you have a method to measure them—radar. What do controllers do when the radar is inoperative for some reason? This is a rare occurrence, but it does happen, and the safety requirement does not go away just because the aircraft cannot be seen on radar anymore. Controllers must resort to using position reports provided by the pilots and the distance reported by the instruments in the aircraft that have distance-measuring equipment, or DME. This measurement is combined with time, altitude, and the use of land-based navigation aids to provide the required increased separation between aircraft. Although safe, this process is extremely slow due to the increased radio communications involved with requesting and receiving position reports and the additional distance required between arriving aircraft when working without the advantage of radar.

Safety in Tower Operations

The most visible of air traffic facilities is the control tower. When most people think of air traffic controllers, they usually think of the controllers in the tower. This seems logical since the control tower is usually seen someplace on the airport and the radar controllers are located in some obscure building out of sight. Just as in radar facilities, the control tower must

exercise safety measures during aircraft movements as well as during interactions with other controllers, both in the tower and in other facilities. Although each facility has its own area of traffic jurisdiction, the tower and radar controllers are constantly working closely together to ensure traffic safety.

The control tower is aware of every aircraft movement that occurs on the airport surface. Even if an aircraft is to be towed from one position to another, the tower must approve the operation. From the time the aircraft is pushed back from the loading gate until it lifts off the runway during its takeoff, it is monitored and directed by the control tower.

The ground controller issues taxi instructions to the aircraft when it is ready to taxi from the terminal loading gate to the departure runway. The aircraft's progress is closely monitored by the ground controller, and the aircraft is informed of any other aircraft and other ground traffic in its immediate vicinity as it moves along. Basically, aircraft on the ground are controlled in the same manner as vehicle traffic on the streets. They are given specific taxi instructions telling them which taxiways to use to get to the end of the runway for departure. Taxiing aircraft are told when to stop and when to go at different taxiway intersections and when to give way to other aircraft as the tower establishes the aircrafts' positions in the departure sequence.

The most critical safety areas on the airport surface are the active runways. Mixing high-speed arriving and departing aircraft using the same surface requires a controller's full and undivided attention. Factoring in the numerous runway crossings, both by taxiing arriving or departing aircraft and by ground vehicles, the runway becomes an area with an extremely high potential for disaster. Literally hundreds of thousands of lives encounter this potentially dangerous environment every day across the nation.

To ensure the safety of the aircraft during runway operations, close interaction and coordination are required between the two air traffic controllers responsible for its success or failure. The ground controller is responsible for the movement of all aircraft on the airport that are not on the runway. The local controller is responsible for all airborne traffic around the airport and any aircraft that are on the runway. Therefore, if the ground controller wants to taxi an arriving or departing aircraft across the active runway, he must first obtain permission from the local controller. The local controller may

instruct the ground controller to hold the aircraft short of the active runway or she may give permission for the aircraft to taxi across the runway.

Regardless of which instruction is given to the ground controller, the instruction is repeated back to the local controller verbatim. This is a built-in safety measure that ensures there is no miscommunication or misinterpretation of the instructions by either controller during this sensitive operation with such a high potential for disaster if mistakes are made. This is one operation that advanced technology has not replaced. There are still certain times in air traffic control when nothing can replace old-fashioned eye-to-eye contact and face-to-face coordination to ensure safety of aircraft involved.

Sequencing and landing the arriving aircraft, as well as clearing departing aircraft for takeoff, is the responsibility of the local controller in the tower. This controller must also adhere to strict safety rules and guidelines when balancing arriving and departing aircraft. Factors such as the aircraft's performance capabilities and potential for wake turbulence must be constantly taken into consideration.

A great amount of skill and judgment is required to perform the duties of an air traffic controller. These attributes, combined with the safety mechanisms the FAA has developed and implemented, make the complex world of air traffic work in a seemingly simple manner.

Air Traffic Controller Training

The training of air traffic controllers is one of the most important issues that the Federal Aviation Administration (FAA) faces today. The primary job of an air traffic controller is to provide a safe, expeditious, and orderly flow of air traffic to prevent a collision between aircraft operating in the national airspace system. Typically, high-traffic workloads can lower performance and set an upper limit on traffic-handling capacity, whereas times when traffic workloads are low can result in boredom and reduced alertness.

One approach to meeting the training need is the use of simulation. By using simulators, controllers gain inherent knowledge of a particular airport, its airspace, and application of air traffic procedures for that specific location. A computer-generated simulation can create multiple air traffic control situations, allowing controllers to respond as they would in a real situation. This method of training is in alignment with pilot training.

Today, with many airlines, a newly hired pilot has already learned to fly, has accumulated the appropriate number of flight hours, and is type-certified prior to being hired. Conversely, air traffic control trainees, or “developmentals,” enter training at air traffic control facilities with basic knowledge. Much of the training at operational facilities is accomplished as developmentals handle live traffic, closely supervised by certified professional controllers. On average, between 1,000 and 2,000 hours of combined on-the-job training and work experience is needed at an en route air traffic control facility or a busy terminal radar facility before a new controller has enough skill and knowledge to attain full certification. Therefore, reducing the amount of time to train a controller without jeopardizing safety is paramount.

Simulation Fidelity

A standard definition of “simulation fidelity” is the degree to which the simulation emulates the real system. Several training sources have provided definitions for “simulation.” These definitions cover basic or part-task simulation, low-fidelity simulation, medium-fidelity simulation, and high-fidelity simulation. Basic or part-task simulation is the imitation of a behavior or task but lacks

functional and environmental fidelity. Essentially, these are systems that do not require visual displays or hands-on control functionality. Low-fidelity simulation is the basic modeling with desktop computers and monitors with some imitation of input devices. Low fidelity may include visual displays or control interaction and has the ability to practice multiple types of errors. Medium-fidelity simulation includes more equipment functionality that does not require visual systems or highly realistic controls. This level of simulation fidelity can be used for practicing procedures such as emergency response and flow controls. High-fidelity simulation is near-system fidelity that can simulate multiple weather environments and the ability to emulate real-world events and features. Some examples of high-fidelity features are generating traffic and aircraft types in high-value training situations like departure overtakes, slow-climbing aircraft, en route overtakes, inverted holding pattern stacks, crossing traffic for departures or arrivals, sequencing problems, sector saturation, scanning complexities, and others.

Simulation Benefits

Any simulation equipment must be able to stimulate the most common cognitive abilities and psycho-motor skills that have been identified in several studies dealing with air traffic control. Cognitive abilities are memory skills, numerical ability, spatial ability, and speed and accuracy in perception. Psycho-motor skills include the effective use of keyboard, trackball, mouse, coordination, and consistency of required actions. In the world of air traffic control training, there are several companies that provide different versions and levels of simulation equipment. These systems allow students to experience the look and feel of air traffic control; the stress of controlling multiple targets and making sure they are separated has tremendous benefits over the old true and tried method of lecture-only sessions. A good simulation product can have a dramatic effect on the entry-level controllers in a number of areas. First, there is safety in the simulation environment. Real-world situations can be programmed into scenarios that allow students to try to work their way out of problems that might be experienced with live traffic. Also, scenarios can emulate situations that are designed to enforce procedures that are unique to

air traffic control and not seen very often. Finally, with the ability to teach procedures, airspace, and techniques, simulation will build confidence in the students and reduce the pressure on them. As with pilots, developmentals, or trainees, can be much better prepared and confident before they actually begin working live traffic. In such a critical part of the American economic infrastructure, the need to train air traffic controllers quickly, efficiently, and safely should far outweigh the costs.

Air Traffic Flow Management

Air traffic flow management (sometimes abbreviated ATFM) is the regulation of air traffic with the objective of avoiding either exceeding or running below the optimal capacity of a given airport. At its most deceptively simple, ATFM is based on the premise that only one craft can land or take off at a given time. When runway capacity is not fully used, passenger delays increase and profitability suffers for a variety of reasons. Conversely, when runways are operated over capacity, the risk of collision and other dangerous events increases. Thus, it is in the best interest of safety and efficiency to regulate with great precision the location of each aircraft on each runway within any given airport.

Safely Maximizing Efficiency

Proper air traffic flow management is, at its core, all about balancing safety and efficiency. The most obvious danger in running above capacity is the risk of collision between aircraft. Simply put, the closer together the moving craft, the higher the risk of collision. The risks associated with running below capacity are less obvious, and they are not nearly as dramatic. From a business standpoint, it does not make financial sense to run fewer aircraft on the airport's runways than the facility is capable of handling. Furthermore, inefficient air traffic flow management can cause significant delays in flight schedules, which can cause systemic delays across a region if delays within a facility become severe enough.

Several factors dictate the maximum capacity of any given facility. First, and most basically, capacity is determined by the number of runways available. The layout of taxi tracks may also dramatically affect facility capacity. Taxi tracks are those runways that

are reserved for short-distance commuter planes. When properly separated from runways for other aircraft, taxis are able to cycle through the facility at a greater rate, and larger planes are able to take off without delays caused by taxis.

Proper air traffic control is the most effective moment-to-moment solution to air traffic flow management. The work of air traffic control staff is to direct traffic in and out of the facility. This is one of the key areas where proper staffing can dramatically affect the capability and safety of an airport. Just as critical as staff is proper air traffic control equipment. Faulty or outdated equipment may also have a detrimental effect on the output of the airport. Finally, weather conditions dictate the capacity of the facility, but proper air traffic control can mitigate even this most chaotic of factors.

The capabilities of air traffic control workers are greatly influenced by capacity. The factors that dictate facility capacity and may be controlled via proper management in the midterm are of special interest to those interested in facility productivity. These factors are understaffing and the continued use of outdated or faulty equipment. Understaffing is the condition of not having enough qualified employees for safe and efficient airport operation. Understaffing is a problem not only at small or low-budget airports; understaffing has been a dangerously serious issue at major airports, including Chicago's O'Hare International Airport. In the early 1990s, O'Hare was the site of one of the most dangerous facility environments in modern aeronautic history. Despite the presence of a unionized workforce and associated staffing regulations, air traffic control staff were forced to work six-day weeks. This dangerous practice has been scientifically shown to contribute to burnout and greatly diminished productivity of the existing workforce. In 1988, 33 incidents occurred in which planes came dangerously close to colliding with each other. Investigations into those incidents showed near collisions to be the result of insufficient staffing combined with the presence of faulty or outdated equipment in the facility.

Since 2000, the U.S. Department of Transportation has been attempting to enact a plan that would replace outdated radar systems with global positioning technology to track aircraft. Despite this initiative, the Transportation Department inspector general issued a report in July 2012 stating that many currently operational air traffic control facilities

are deteriorating and outdated. In that report, he called on the agency to accelerate its current 20-year upgrade plan, which is slated to be complete by 2020.

The condition of aircraft operating dangerously close to each other is not caused only by understaffing or faulty equipment; aircraft can also be forced dangerously close together in the name of maximizing profits. Since the majority of airports worldwide are for-profit ventures, and profit in the modern airline industry is dependent on running at maximum capacity, there is often pressure to push that maximum capacity as far as it possibly can go. Unfortunately, such a mind-set can get in the way of good reason or safety. Running over maximum capacity can result in low-altitude midair collisions, head-on or side-on runway collisions, forced takeoffs during inclement conditions, and even incidents involving animals or individuals on the tarmac.

What Can Be Done

Modern airlines operate their business models on an assumption of airports running at maximum capacity. Unfortunately, these models often do not put safety or comfort of the passenger first. Given this assumption of maximum capacity, air traffic often exceeds what can be effectively handled through a proper ground delay program. In this process, planes are assigned positions in a takeoff queue, and the queue is run through as aircraft are able to take off.

When the ground delay program is not sufficient to maintain air traffic flow, in-flight holding patterns may be established. These holding patterns require airborne planes to circle the airport in a queue-type system similar to the ground delay program. Thus, as long as airlines are motivated by a profit motive that causes them to strive for runway maximization, passengers may be stuck with delays, holding patterns, and potentially dangerously congested runways for the foreseeable future.

Air Travel

Studies in air travel behavior seek to understand passengers' long-distance travel choices. Passengers make numerous choices when planning their long-distance travel. For example: Which destinations do people consider when planning their trip? Do people consider traveling only by air or consider other modes of travel as well? If travelling by air, do people search for alternatives at one airport or multiple airports? If driving to the airport, where do people park? How much are people willing to pay to fly during peak travel periods? A better understanding of how long-distance travelers make these and related choices helps airlines, airports, government agencies, financial institutions, and other decision-making entities evaluate infrastructure investment alternatives, marketing initiatives, operational strategies, and numerous other proposals.

The types of research questions that are investigated often depend on the decision makers' perspectives. Airlines are generally focused on maximizing net revenue through attracting new customers and retaining current customers while ensuring safe and efficient operations. In contrast, airports and government agencies are generally focused on predicting demand for existing and proposed transportation alternatives. A broad range of proposals may be considered and may include new infrastructure (for example, constructing a rail line to a secondary airport or constructing a new runway), landside operational improvements (for example, building a new parking facility), or the introduction of new taxes, credits, or other policy instruments.

Data

Given the different perspectives among decision-making entities, it is not surprising that the data used for analysis also differ. Within aviation, the strong operational focus has resulted in decision-support models based almost exclusively on revealed preference data. Revealed preference data capture actual passenger choices under current and prior market conditions. Given the dynamic nature of the airline industry and the need for airlines to identify and respond quickly to changes in competitive conditions, many airlines have invested in decision-support models that rely heavily on recently observed revealed preference data.

Stated preference data are also used to understand air travelers' behavior. Stated preference data are collected via surveys that ask individuals to make hypothetical choices among different alternatives. Stated preference data are particularly useful when investigating customer response to new products or transportation alternatives. For example, in the United States, Resource Systems Group has conducted an annual survey of air travelers since 2000. This annual stated preference survey has been used by airlines to assess the potential of new or enhanced products (for example, cabin service amenities, baggage fees, and customers' willingness to pay for shorter connection times). Government agencies have also used this stated preference panel data to investigate changes in passenger behavior after 9/11.

Methodologies

Some of the most popular statistical techniques used to model air traveler behavior studies include regression, count, time series, and discrete choice models. The selection of a particular model depends on the objectives of the research and available data. For example, regression or count models can be used to represent the number of purchases made for a flight or for multiple flights serving the same market (or airport-to-airport pair). Time-series methods can also be used in this context to account for trends, seasonality, and other fluctuations in demand.

Discrete choice methods differ from the techniques above in that they incorporate information about how individuals make tradeoffs among different attributes when making a choice among a set of alternatives. For example, when deciding which

mode of transportation to take to the airport, passengers may make tradeoffs among time, cost, and convenience associated with different alternatives. When deciding which flight to purchase, passengers may make tradeoffs among the prices, departure times, level of service (nonstop versus connecting), and other flight attributes.

Research Directions

Multiple factors have contributed to the current state of the airline industry, including the emergence of online travel agencies (OTAs) that facilitate the comparison of prices across airline competitors, the increased market penetration of low-cost carriers (LCCs), industry consolidation, and the introduction of new ancillary fees. All of these factors have influenced current research in air travel behavior.

Within the airline community, these changing market dynamics have led to interest in using discrete choice models to forecast demand for revenue management (RM) systems. Conceptually, choice-based RM methods use data that effectively track individuals' purchase decisions. This could potentially include the menu of choices customers viewed prior to purchases. That is, in contrast to traditional booking data, online shopping data provides a detailed snapshot of the products available for sale at the time an individual was searching for fares, as well as information on whether the search resulted in a purchase (or booking).

The availability of Internet data is leading to research on how information about competitors' products and prices can be integrated into demand forecasts. This is viewed as important, as approximately 60 percent of online leisure travelers purchase the lowest fare they can find. Understanding how customers search and purchase online is an active area of research, as is developing models that incorporate individuals' willingness to pay for product attributes, particularly with respect to competitors' offerings.

Understanding the influence of social media and mobile devices on air traveler behavior is another active area of research. Social media sites enable travelers to share their experiences. Future travelers can use these sites to gather recommendations on where to travel, which modes of transportation to use to reach the destination, which sites to visit once they are at the destination, etc. Mobile devices

provide the opportunity to send real-time information to travelers. This information can include real-time airport parking availabilities, automated baggage tracking, and communication of flight delays. This information allows customers the ability to alter their travel plans.

In the late 2000s, many airlines started creating new products and ancillary revenue streams. New fees were introduced to check bags and reserve coach seats. In addition, many existing ancillary fees were increased (for example, fees for redeeming mileage award tickets, on-board checked pet fees, unaccompanied minor fees, in-flight entertainment fees, food for sale). The impact of these fees on air traveler behavior is currently not well understood. For example, are customers sensitive to baggage fees and will people fly on a nonpreferred carrier to avoid these fees? Do customers view seat displays when they are selecting their itineraries and will they choose a different flight (or a different carrier) if only middle seats are available to reserve for free? Understanding these and related questions are another active area of research that has been of interest to both airlines and government agencies. Government agencies are interested in ensuring that ancillary fees are clear to consumers at the time of purchase. Government agencies are also interested in quantifying potential dilutions to tax revenues (many ancillary fees are not subject to taxes in the United States).

The impact of industry consolidation on consumer welfare and regions served by small airports is an example of ongoing research that has been of particular interest to government agencies and airports. In recent years, service to smaller airports has been reduced (or eliminated). In part, this is due to increased fuel prices, which has made it unprofitable for airlines to operate regional jets into these areas. Airports and small communities are developing strategies to quantify the economic impacts of these service reductions and to evaluate different proposals for mitigating these negative impacts. For example, should a small community offer financial incentives to an airline for maintaining air service, or would it be better to initiate bus service to a major airport hub instead?

Air Travel Regulations, History of

When Orville and Wilbur Wright made the first successful powered airplane flight in North Carolina on December 17, 1903, they heralded a new age of human transportation. People had been going aloft in hot-air balloons for over a century, especially in Europe, but the capacity of balloons to carry significant numbers of passengers efficiently for any real distance was limited. Within 20 years of the Wright brothers' achievement, however, that had changed, and aircraft were carrying supplies, packages, and people.

Notable accidents, incidents of mismanagement, and air traffic confusion, however,

necessitated planning of air service and air routes as well as professional air traffic control. Burgeoning airlines also had to learn how to efficiently move passengers with ease and safety. As such, the planning and policy of air traffic dovetailed with the transportation expansion that had begun in the United States and Great Britain with railroads, and with the regulatory age of the American Progressive Era.

World War I, which began just 11 years after the Wright brothers' first flight, proved the ability of aircraft to carry heavy loads and multiple people. While they lacked any real tactical doctrine, British and German air forces flew bombers on missions that were the great ancestors of the 1,000-plane raids of World War II. By the end of the war, however, planes were graduating from multiwing to single-wing designs, and aeronautical designs were enabling the construction of stronger craft.

The immediate postwar years saw the barnstorming days of aviation. Pilots, most trained in the war, put on air shows, carried bags of mail, and, depending on the capacity of their aircraft, could carry a passenger or two from place to place.

Navigation was rudimentary, with pilots using cheap compasses or flying low enough—rarely more than 500 feet up—to follow roads on the ground. Lack of plane instruments meant all flying was VFR (visual flight rules) even in bad weather. Crashes were plentiful.

First Regulations

The U.S. Congress passed the Air Mail Act of 1925 (also known as the Kelly Act), authorizing the federal government to let contracts for air-mail delivery. With 80 percent of stamp receipts going to airmail carriers, the federal government was effectively subsidizing the start of an American airline industry. The Department of Commerce handled what little regulation went with the 1925 act.

Federal aviation regulation followed the precedent-setting legislation of the American Progressive Era. During those years, roughly 1900 to 1916, the U.S. Congress approved regulation of the food and drug industries, workplace safety, and child labor.

In 1926, recognizing the need for more regulation, Congress passed the Air Commerce Act. It required regular inspection and maintenance of aircraft, fuselage and wing markings for recognition,

altitude separation in flight, and knowledge and physical exams for pilots. It also tasked the Commerce Department with the construction of airfields and the implementation of takeoff and landing procedures and air traffic control systems. The Department of Commerce created its own Aeronautics Branch to handle the new responsibilities. In 1934, the Aeronautics Branch became the Bureau of Air Commerce.

Increased passenger traffic led inevitably to increased fatal crashes in the 1930s. In the United States, more than 100 people died in accidents, including one that killed famed Notre Dame football coach Knute Rockne in Kansas in 1931. Other celebrity air crash deaths in the 1930s included New Mexico Senator Bronson Cutting in 1935 and filmmaker Martin Johnson in California in 1937. Global air fatalities topped 200 in the 1930s.

In 1938, Congress passed the Civil Aeronautics Act, which created the Civil Aeronautics Authority (CAA). The CAA would regulate air rates (the federal government had been doing something similar with railroad freight rates since 1887), regulate air routes; investigate aviation accidents, and look for ways to increase air safety.

Two years later, President Franklin Roosevelt split the CAA into two agencies: the Civil Aeronautics Administration (still the CAA) and the Civil Aeronautics Board (CAB). The CAA took responsibility for air traffic control (previously a state responsibility in most airport towers), pilot training, and air routes; the CAB handled safety regulations and accident investigations.

The CAA quickly set about planning for airfield modernization programs. In 1944, with the end of World War II imminent, the CAA submitted a report called the "National Airport Plan." Congress approved it in 1946 with the passage of the Federal Airport Act. It authorized the expenditure of \$500 million over the next seven years to update airfield runways, taxiways, lighting systems, and other essential airport systems. The legislation was updated to varying degrees through 1970.

Disaster Speeds More Regulation

On June 30, 1956, a Trans World Airlines (TWA) Lockheed Constellation and a United Airlines DC-7—both four-engine, propeller-driven aircraft (the Constellation with a distinctive tri-rudder design)—left Los Angeles Airport within

three minutes of each other. The TWA, Flight 2, was bound for Kansas City, the United, Flight 718, to Chicago. The TWA plane flew at 19,000 feet, and the United aircraft was 2,000 feet above it at 21,000 feet.

As both aircraft neared the Grand Canyon, they flew into rough weather and clouds. The captain of TWA 2 requested permission to climb to 21,000 feet, but air traffic controllers denied the request, given that United 718 was at the same altitude. The TWA captain asked to get 1,000 feet above the clouds and go on visual flight rules (VFR). Air traffic control (ATC) then assumed that both aircraft would be able to see each other. With both planes on VFR, air controllers had no further responsibility to monitor the craft.

At about 10:30 A.M., the planes collided over the Grand Canyon. The DC-7 hit the Constellation's tail, and its propellers ripped open the TWA plane's body. The Constellation's tail severed and began to fall; the front of the plane dived nose first into the canyon. The United flight also plummeted, hitting the top of a nearby mesa. One hundred twenty-eight people died.

The crash prompted a massive \$250 million overhaul of the nation's air traffic control system. The federal government also responded with the creation of the Federal Aviation Administration (FAA).

In 1958, Congress created the FAA, which took over responsibilities from the CAA in stages. Under President Lyndon Johnson, the FAA became the Federal Aviation Administration in 1967 and became part of the presidential cabinet-level Department of Transportation (DOT). At the same time, the CAB became the National Transportation Safety Board, still tasked with investigating accidents.

The FAA continued updating ATC systems, establishing the Air Traffic Control Systems Command Center, the Central Flow Control Facility, the Airport Reservation Office, the Air Traffic Service Contingency Command Post, and the Central Altitude Reservation Facility in 1970 to deal with increased airline traffic and passenger usage.

Air Traffic Controllers' Strike

Air traffic controllers working for the FAA sought unionization in 1968. The Professional Air Traffic Controllers Organization (PATCO) became their bargaining agency. After failing to receive an acceptable new contract in 1981, more than 12,000 of the

15,000 PATCO members went on strike, grounding 35 percent of the nation's daily air traffic.

President Ronald Reagan, recognizing the economic consequences of grounded commercial flights, gave the air traffic controllers 48 hours to return to work. When they did not, he fired them. FAA supervisors and military air traffic controllers stepped in to keep U.S. air traffic moving. PATCO eventually dissolved; air traffic controllers did not have union representation again until 1987.

Airport Physical Maintenance

The FAA also has control of the physical standards and maintenance of American airports. It oversees such areas as firefighting and rescue squads at airports, runway lighting systems, runway debris cleanup, and signage. It also looks for ways to mitigate wildlife strikes, that is, aircraft hitting birds, bats, or even turtles on runways. Who can forget pilot Chesley Sullenberger successfully ditching his US Airways Airbus A320 in the Hudson River after hitting a flock of Canada geese on takeoff from New York's LaGuardia Airport in 2009?

The FAA also analyzes growth patterns in airline usage and, based on projections from that information, it looks at current capacity limitations of airports. It then suggests plans for building and renovation projects to meet future needs.

Among its long list of tasks, the FAA is also responsible for reducing aircraft emissions and limiting "noise pollution" from aircraft, especially over residential areas. Airport building designs must be environmentally sensitive, and the FAA must provide relocation assistance for people being moved due to airport renovation projects.

Air Terrorism

The first apparent act of air terrorism occurred on October 10, 1933, when a nitroglycerin bomb blew the tail off a 10-seat United Airlines Boeing 247 over Chesterton, Indiana. The plane crashed, killing all seven of the passengers and crew. The incident remains officially open, but investigators quickly suspected a Chicago gangland connection. An investigation diagram published in 2011 by *chicagomag.com* suggests that the bomb was placed amid some blankets in a baggage compartment near the rear of the plane. Two passengers fell from the plane when the tail fell away. They and the tail wreckage landed some 50 feet away from the main

fuselage. The bomb may have been intentionally exploded, or someone trying to secretly transport the device may have hidden it and it exploded prematurely. Regardless, air travel had entered the age of air terrorism.

The Web site *aerospaceweb.org* lists 88 air incidents caused by onboard bombs; 56 of these caused 2,790 fatalities (not counting ground fatalities on September 11, 2001). At least six of the bombings were presumed motivated by insurance payoffs to beneficiaries of the bombers (as was depicted in the popular 1970 movie *Airport*). Most of the other incidents had political motivation, either by agents of some political movement or by lone bombers acting for a political cause.

The most notorious air terrorism incident is, of course, the 9/11 attacks on New York and Washington, D.C. Members of the radical Islamic jihadist group Al Qaeda boarded four United and American Airlines aircraft on September 11, 2001, hijacked them, and flew them toward their targets. Two of the aircraft smashed into the Twin Towers of the World Trade Center in Lower Manhattan, New York City. They ignited fires that caused the buildings to collapse. Terrorists flew another into the Pentagon building in Washington, D.C.; another group was apparently flying to a Washington target when passengers overthrew them and flew the plane into the ground near Shanksville, Pennsylvania, rather than allow the terrorists to reach their objective. Total fatalities were near 3,000, both on the aircrafts and on the ground.

Prior to 9/11, the worst case of air terrorism occurred on June 23, 1985, when members of a Sikh separatist group known as Babbar Khalsa planted a bomb in the forward baggage hold of an Air India Boeing 747. The bomb exploded when the aircraft was over the Atlantic Ocean just south of Ireland. The plane decompressed and fell apart, killing all 329 people aboard. Other members of Babbar Khalsa intended to bomb another Air India plane scheduled for takeoff from Tokyo, but their bomb went off on the ground, killing two baggage handlers.

Just as infamous was the December 21, 1988, bombing of Pan Am Flight 103, a Boeing 747, over Lockerbie, Scotland. American and British investigators determined that Libyan radicals had set the bomb that killed 270 people, including 11 people on the ground.

Responding to the Threat: Air Marshals

In 1961, after a series of hijackings in which Cuban émigrés, or expatriates, diverted American commercial flights to Communist Cuba, President John F. Kennedy announced that sky marshals, whom he called “border patrolmen,” would be randomly flying on passenger flights to deter further incidents. (President Kennedy also directed that flight deck crews lock the flight deck doors and keep the keys with them.)

The number of skyjackings rose to more than 75 by the late 1960s, prompting the U.S. Customs Service, which oversaw the air marshals program, to train nearly 1,800 new marshals. However, the program was seen as ineffective, and the number of marshals in service reportedly dropped to near 30 in the early 1980s.

In 1985, members of the radical Palestinian group Hezbollah skyjacked TWA Flight 847 and diverted the plane to Beirut, Lebanon. They held it for a 17-day siege in which one American died. The incident prompted President Reagan to again build up the air marshals service and add agents to international flights.

Decreased skyjackings in the 1990s caused the air marshals program to flag once again, but 9/11 changed that. In a fear-driven reaction to the al Qaeda attacks, Congress created the Transportation Security Administration (TSA) and placed it within the new cabinet-level Department of Homeland Security. With new budgetary allocations, the TSA reportedly hired nearly 4,000 air marshals.

Airport Security

Air marshals, however, were never the only defense against air terrorism, and airports in the 1960s began rudimentary efforts to prevent weapons from being taken aboard flights. The most noticeable security additions at U.S. airports, as well as around the world, in the 1970s were metal detectors. Before entering boarding areas, passengers were required to pass through the detectors. Frequent flyers became accustomed to the ritual of removing their watches, eyeglasses, and belts as well as emptying their pockets of change to avoid setting off the detectors.

As in other facets of air security, 9/11 upped the ante. For months after the terrorist attacks, Americans saw armed National Guardsmen at airports, and they had to affirm that their luggage had never

left their possession since arriving at the airport. After passengers caught radical Islamist Richard Reid trying to light explosive in his shoes in a post-9/11 flight, air passengers also became accustomed to removing their shoes for inspection before entering boarding areas.

Although luggage had been X-rayed for many years, by 2012 American passengers were becoming concerned over random or required subjection to sensitive full-body scans that could reveal privacy-invading images.

The TSA sees these and other measures as “layers” of security. The agency, in fact, has 20 such layers: intelligence; customs and border protection; a joint terrorism task force; no-fly lists and passenger prescreening efforts; the vetting of crew members; Visible Intermodal Protection and Response (VIPR), trained units fielded to examine trains, ferries, cars, and other modes of transportation that could serve as conduits of terrorists and weapons to airports; explosive- and chemical-sniffing canines; officers trained to detect suspicious behavior; travel document checkers, checkpoints, and transportation security officers; baggage checks; transportation security inspectors; random employee screening; bomb appraisal officers; air marshals; federal flight deck officers on aircraft; flight crews trained in terrorism responses; law enforcement officers; hardened cockpit doors; and alert passengers.

The layers overlap. The TSA proclaims the following on its Web site:

Each one of these layers alone is capable of stopping a terrorist attack. In combination their security value is multiplied, creating a much stronger, formidable system. A terrorist who has to overcome multiple security layers in order to carry out an attack is more likely to be pre-empted, deterred, or to fail during the attempt.

Israel, the target of Islamist, Arabic, and Palestinian attacks since it became a nation in 1948, has long been the acknowledged master of airport and airline security. *International Policy Digest* reports that at Tel Aviv’s Ben Gurion Airport, Israel employs a vast array of techniques—from constantly operating television monitors and scans of vehicles and passengers to patrolling armed guards, some of them in plain clothes. But Israel places a premium on interviews with people arriving at airport parking

NASA and the Federal Aviation Administration began using this lunar excursion module facility built for the Apollo program as a general aviation aircraft crash testing facility in 1972. At the Impact Dynamics Research Facility, aircraft swing on cables in the 400-foot-high structure to create controlled crashes that help researchers improve airplane safety and passenger survival rates.

areas and with passengers either arriving or departing by plane. The interviewers are well trained and encouraged to follow “gut instincts” that might be alerted by suspicious behavior or body language. Allegations of racial or ethnic profiling do not deter the security experts.

In Europe, the European Commission, European Aviation Safety Agency, and EUROCONTROL jointly manage airplane and airport security. The combined agencies work much like the FAA and TSA in the United States. EUROCONTROL is committed to a “Single European Sky” initiative, which endeavors to seamlessly integrate air traffic standards across Europe. Similar agencies work to coordinate air security in Asia.

In Africa, however, airport and airline security remain problematic. In December 2009, the arrest of a Nigerian who tried to detonate explosives as his plane from Amsterdam landed in Chicago ignited concerns about African airport security. Both the United States and the European Union were concerned about substandard equipment and practices at African airports. At the time of the failed attack,

the *Wall Street Journal* reported that the European Union had forbade at least five African airlines from flying into Europe, and only one U.S. airline serviced sub-Saharan Africa, all because of safety concerns. The TSA has endeavored to work with African airports and airlines to improve coordination.

Open Skies

Security concerns aside, the U.S. Department of State has put together an initiative to facilitate broader air commerce between the United States and the rest of the world. From the early days of mail transport to modern passenger conveyance, civil air travel has always been about commerce.

According to the State Department, open skies agreements

... expand international passenger and cargo flights by eliminating government interference in commercial airline decisions about routes, capacity and pricing. This frees carriers to provide more affordable, convenient and efficient air service to consumers, promoting increased

travel and trade and spurring high-quality job opportunity and economic growth. Open Skies policy rejects the outmoded practice of highly restrictive air services agreements protecting flag carriers.

As former Secretary of State Hillary Clinton said,

Work to “democratize” aviation continues to allow millions more Americans the opportunity to fly to international destinations each year and for countless foreign tourists to visit our country.

The State Department estimates that an open skies agreement can generate as much as \$720 million for each of any two terminal points in the United States and overseas.

Aircraft, New Large

In the 21st century, airlines and aircraft manufacturers have been building new large aircraft that weigh over 1 million pounds, cost billions of dollars to manufacture, and can carry between 500 and 1,000 passengers. The Federal Aviation Administration (FAA) calls airplanes like the Boeing 747-400 and the Airbus A380 New Large Aircraft (NLA). The NLAs have significantly wider wing spans, taller tail sections, longer fuselages, heavier taxiing weights, and the ability to transport large number of passengers.

Airlines believe that NLAs will allow them to make larger profits and reduce operational costs by carrying more people in fewer airplanes. As the NLA industry expands, it is having substantial impacts on existing airports and terminal operations, particularly individual passenger processing facilities. Many airports will need major facility improvements to handle NLAs, with the majority of the changes being expensive upgrades to meet FAA Design Group VI standards for most New Large Aircraft.

The Federal Aviation Administration, NLAs, and Airports

Most existing airports will have to address operational challenges to accommodate the new generation of NLAs on the airside and on the terminal side of the airport, and if they are not successfully resolved, they might prevent NLAs from operating at many airports. Forced upgrades will evidently be more expensive for older, crowded airports without any room left for expansion. Airbus suggests that upgrading airports may not be such a monumental task, claiming that the cost of upgrading existing airports to accommodate larger aircraft and their expanded passenger capacity reaches the hundreds of millions of dollars, but building new

airports will cost billions of dollars. According to this rationale, using NLAs is still more economical, even if an airport has to absorb the cost of adapting existing infrastructure.

The impacts of the NLA on airports affect airside and passenger terminal planning. The airside issues focus on airfield geometry or the size and separation of taxiways, runways and aprons, which the large dimensions of the NLAs will impact. The dimensions of the NLAs also impact system capacity and the structural design of the airfield pavement. These are crucial operation issues for the airport system.

Airside: Runway Issues

In its report titled *Impact of New Large Aircraft on Airport Design*, the FAA states that all airlines will be affected by NLAs if they choose to allow them to fly in and out of their airports. The airside impacts of airport accommodation for NLAs include geometric design of runways and taxi ways. The number of arrivals and departures on a runway during any hour depends on the mix of aircraft that use the runway. If the mix includes one or a few NLAs, the capacity will be lower than at times when the mix is made up of smaller aircraft. Large NLAs also produce wake vortices that may be a danger to planes flying right behind them.

The Federal Aviation Administration establishes runway requirements for airplanes. The A380, the first aircraft in FAA Design Group VI, has a wingspan of nearly 262 feet, and airports that serve the A380 will have to meet FAA requirements for this category as well as for runway and taxiway widths. Runway-to-taxiway and taxiway-to-taxiway separations will also need to be increased.

The NLA will impact runway design, including length, width, shoulders, blast pads, and stop ways. The aircraft weight has a great effect on the runway length. The greater the total weight (operating weight empty plus payload plus fuel) of an aircraft, the longer are the takeoff and landing distances. Longer stage lengths mean more fuel, increased weight, and longer takeoff distances. With its massive body weight, an A380 needs to operate on a longer runway to perform safely.

The U.S. Department of Transportation says that when airplanes are taking off and landing, the air traffic management requires a longer separation between pairs of successive aircraft when the first

This 2011 view from inside the terminal at Washington-Dulles International Airport shows a double-decker Air France Airbus 380 with two passenger bridges, numbered A20 and A22, attached at different levels for faster passenger transfer.

aircraft is a large and heavy airplane. Two NLAs rarely will take off or land as a pair, and the NLAs would have to be scheduled to avoid peak hours to ensure the maximum runway capacity for the busiest periods at the airport. FAA Advisory Circular 150/5325-4 sets forth detailed methods of calculating runway length and the calculations match the NLAs' runway length requirements with the B747-400, implying that any airport that can accommodate a B747-400 will require no further modification of runway length.

NLA Scheduling

Aircraft scheduling and capacity planning are meant to enhance gate efficiency and profits, and NLAs impact both. To avoid high passenger volume, airports can schedule NLAs to land or take off during off-peak hours, but this is contrary to the hub-and-spokes system, which is one of the results of the deregulation of U.S. airlines. Before hub-and-spokes, airlines operated with point-to-point routes

that often were not cost efficient. The hub-and-spokes system concentrates traffic in one airport as a major hub and collects passengers from smaller national airports known as the spokes; the gathered passengers are flown from the major hub to another major hub. Off-time flights also conflict with overseas time slots.

Emergency Plans

The Federation Aviation Administration design standards for airport emergency plans are spelled out in Aviation Regulations and Advisory Circulars, especially FAA Advisory Circular 150/5200-31. The increasing presence of NLAs makes it necessary for certain areas of airport operations to be reviewed, including fire protection and equipment and emergency procedures. The size and physical characteristics of NLAs determine the composition of the rescue and firefighting equipment at the airport. Airport firefighters will need longer ladders and other specific types of equipment to fight fires in the multiple-occupancy-level NLAs.

New Large Aircraft carry 20 to 30 percent more passengers and require airports to have additional emergency equipment, supplies, and personnel to respond to an emergency. The U.S. Department of Transportation predicts that if airports practice a full-scale emergency plan drill once every three years, the airports that serve NLAs will experience a significant increase in the number of participants and the possibility of chaotic situations.

Landside and Terminals

The high passenger capacity of NLAs eases the airside operation congestion but paradoxically creates terminal and landside congestion that may force airports to double the size of their waiting lounges and increase ticket-processing capacity. Airlines will have to expand baggage handling and customs areas and widen car park and taxi waiting areas as well and still might not even be able to handle the surges of arriving and departing passengers.

New Large Aircraft feature double-decker designs that will impact airport design and operating requirements. To keep competitive airline schedules and restrictive takeoff and landing slots, double-decker airplanes like the A380 are designed to connect three passenger bridges to meet the 90-minute turnaround demand. Many existing

terminals will have to be structurally modified to use upper-level bridges.

Plans for new airports and expansions at existing airports already take the proposed NLAs into consideration, but these aircraft may be able to operate at some facilities with modifications to taxiways and operations. The FAA identified five main issues related to the NLA and their compatibility with airport terminals. One of the issues is the number of gate positions needed for NLAs. Providing exclusive use gates for NLAs is very expensive because of their dimensions and the need for large amounts of physical space. Terminal configuration is an important component of modification or building for NLAs.

Another issue is the design and sizing of the departure, or gate, lounge, the buffer where passengers wait to board their flight. New Large Aircraft feature a passenger capacity up to 64 percent greater than older-generation airplanes like the 747. New Large Aircraft have motivated airlines to create ways of economically and efficiently accommodating passengers in the departure lounge. More passengers mean more baggage and higher flows of both passengers and baggage in the terminal. New Large Aircraft have made it necessary for airlines to formulate plans to incorporate new technologies to facilitate baggage check-in, security checks, customs, immigration, and baggage handling.

Aircraft, Regional Jet

Regional jets (RJs) are turbofan (a type of small jet engine)-powered airliners that are capable of short- and medium-range flights. Regional jets are produced in Russia, Germany, Canada, Brazil, Japan, the Netherlands, the United Kingdom, and the Ukraine. Given the diversity of countries that produce these vehicles, it is not surprising that they come in a variety of sizes. Regional jets come in three sizes with anywhere from 27 to 130 seats, differentiated by how the seats are situated in the passenger cabin: three abreast, four abreast, and five abreast. Early RJ technology was first developed in the Soviet Union. Once Western observers recognized the potential of the technology, it was adapted to meet the needs of Western markets. Once adapted, RJs changed air travel by fundamentally altering the paths people travel through the sky by focusing on the fuel efficiency and takeoff power granted them by their

turbofan engines. Due to poor public perception of RJs, airliners have been forced to address issues such as legroom and other amenities. However, despite public relations issues, regional jets remain a cornerstone of the airline industry.

History and Development of Regional Jets

Over the course of the 20th century, social forces increasingly called for the development of light airplane technology. This resulted in the development of faster, smaller aircraft that would enable certain segments of the population to establish weekly commutes via aircraft. Aviation in the first half of the 20th century was dominated by prop planes, which are airplanes that are pushed forward by propellers affixed to either their nose cones or their wings. The advent of turbofan (or fanjet) technology following World War II revolutionized air travel. The term *turbofan* refers to a gas turbine engine that takes mechanical energy from combustion and a ducted fan. The mechanical energy from the turbine then accelerates air rearward to propel the aircraft forward.

The first vehicle that could be considered a regional jet was the Soviet Aeroflot Yakolev Yak-40. This jet was first built in the Soviet Union in 1967. The Yak-40 was used extensively throughout the Soviet bloc and Europe; it was also used in a number of Soviet-allied countries outside Europe. The Yak-40 was essentially a shortened jet with engines on either side of the fuselage and one affixed to the tail. It also featured an integrated tank that provided fuel for each engine and a cabin with seats five abreast. Despite the success of the Yak-40 in the Soviet bloc, it did not meet American or western European needs. The Yak-40 was designed to service areas with less than average air traffic; for this reason, it was little more than a shortened jet with fewer seats. American needs, in contrast, required craft that could move as many passengers as possible over short distances with as great a fuel efficiency as possible, as opposed to moving a few people over great distances.

The need for smaller, more fuel-efficient jets in North America expanded considerably after 1978. That year, the U.S. Airline Deregulation Act phased out the Civil Aeronautics Board with the objective of creating an air transportation system that would be more reliant on market forces. Due to deregulation, airlines were able to create many shorter

A Brussels Airlines British Aerospace 146 (BAe 146) regional jet landing at London Heathrow Airport in 2010. The BAe 146, while no longer made, remains especially popular with European airlines for service between small European cities, as regional jets allow for bypassing of larger airport hubs. As of 2013, regional jets like the BAe 146 were the only service option at 484 world airports.

routes to replace the few longer routes that existed previously. Prior to deregulation, airlines operated from a “hub-and-spoke model” in which all passengers were required to go through a few large airports and then travel to their final destination through feeder routes. Regional jets allowed for direct flights from city airport to city airport; thus passengers were able to bypass hubs. After deregulation, many regional airlines were created that specialized in the use of regional jets.

The first regional jet to be specifically designed for Western use was the British Aerospace 146 (BAe 146). This model was built between 1983 and 2001 in the United Kingdom by British Aerospace. The BAe 146 was specifically calibrated to serve travelers who wished to fly from city-center to city-center. As a result, the BAe 146 was designed to minimize noise and maximize takeoff performance. British Aerospace based much of the marketability of the jet on the fact that it was much quieter than its competitors and marketed the plane under the name *Whisperjet*.

Though manufacture of the BAe 146 was discontinued in 2001, it remains in service by some of Europe’s most notable airlines. This jet is widely used in small city-based European airports by airlines

including CityJet, Swiss European Air Lines, Brussels Airlines, Airlink, and Lufthansa. The jet comes in three sizes (BAe 146-100, BAe 146-200, and BAe 146-300). This plane is also known for its high degree of versatility, and it has been modified for purposes such as firefighter tankers, troop transports, and service as one of Queen Elizabeth’s luxury jets.

Contemporary Use of Regional Jets

The number of passengers serviced by regional jets doubled between 2000 and 2010 for a total of 159 million passengers. Over the past decade, RJs have proven to be critical to the airline industry’s strategy of attempting to efficiently match demand with seat capacity, thus avoiding empty seats. Another reason airlines favor RJs is because they make it possible for larger airlines to outsource to smaller carriers, thus taking advantage of the lower paid workers who are employed by those smaller carriers. At the time of this publication, regional airlines provide the only service at 484 airports.

Regional jets are not without their problems. While highly reliable and safe, RJs have both real and perceived issues. The transition to regional jets was at its highest and most popular within the industry in the 1990s. Since then, customers, especially frequent

fliers, have started to demand more than these traditionally spartan aircraft have offered. RJs are often criticized for being bumpier and experiencing a greater level of cabin noise from their engines. Additional complaints have been leveled because these planes are too small to facilitate either first or business classes or because they do not offer hot meals. In response to these complaints from frequent customers, some airlines have responded by transitioning toward larger regional jet models to minimize these most common size-related concerns.

Aircraft, Very Light Jet

A very light jet (VLJ), as defined by the National Business Aviation Administration (NBAA), is a jet airplane approved for single pilot operation and with a takeoff weight of 10,000 pounds or less. VLJs, also known as microjets, generally have four to six passenger seats, can be piloted by one or two individuals, and are the smallest and least expensive type of jet aircraft on the market. VLJs are intended for the private aviation market and are best suited for use between noncommercial airports because they are able to take off and land from shorter runways than commercial airlines. There was enthusiastic support for the VLJ leading up to and immediately after introduction of the

first working planes in 2007, which were predicted by some to revolutionize the airline industry, but this enthusiasm has since been tempered by the difficulties of making this type of plane safe and economically viable, and many manufacturers who planned or introduced VLJ models have since ceased production of them.

Origins

In the early 2000s, many articles were written predicting that the VLJ would revolutionize air transportation, at least for business class customers, by facilitating jet air taxi services that would combine the convenience of a private, point-to-point air service (allowing the customer to avoid the hassles of using commercial airports and scheduled flights) with the speed of jet aircraft. However, the history of VLJs is marked by large quantities of hope and hype, followed by disappointment as the actual VLJs did not live up to the world-transforming potential that had been imagined for them. The first working VLJ was the Eclipse 500, developed by Eclipse Aviation in Albuquerque, New Mexico. The plane received provisional certification from the Federal Aviation Administration (FAA) in July 2006, and the first Eclipse 500 was delivered in January 2007 to David Crowe and Jet-Alliance, a shared-jet operator in California. At the time, VLJs were heralded by many as the wave of the future, and in 2007 the FAA predicted that 5,000 VLJs would be in use within the next 10 years.

Safety Issues

The Eclipse 500 was plagued with mechanical problems, and in June 2008, the FAA gave an emergency order that all Eclipse 500 planes be grounded. The precipitating incident was a June 5 incident at Midway Airport in Chicago, in which the throttle on a nearly new Eclipse 500 jammed as the pilots were attempting to land the plane, operated by Jim-sair Charter and Management. The FAA ordered inspection of the Eclipse 500's throttle lever mechanisms and investigation of another flaw, a computer error in the plane's controls that appeared to be the cause of the pilot's losing control of one of the plane's engines.

The design and production of the Eclipse 500 had been plagued by many difficulties, and in 2008 Calvin Scovel, inspector general of the Department of Transportation, accused the FAA of rushing the

plane through the certification process while it still had serious safety concerns, including malfunctions of the cockpit displays, falling wing flaps, and delivery of erroneous stall warnings. One major change, introduced relatively late in the design process, was switching engine types. Originally, the planes were intended to use Williams engines, but those engines proved to be too underpowered to allow the plane to meet FAA standards, and Pratt & Whitney engines were substituted. The change in engines required other design changes to reduce drag, increase the size of the fuel tanks, and meet lightning strike standards.

The experience of flying a VLJ is different from that of flying either a large jet or a small propeller plane, and Barbara Burian and Key Dismukes highlight some differences that should be considered when training pilots accustomed to other types of aircraft to fly VLJs. One obvious difference is the fact that many VLJs will in fact be flown with only one pilot (although the plane design may allow for two pilots), so particular attention must be devoted to the resources that will be available to the single pilot and how they could best be used (for example, a passenger could handle and fold charts). A single pilot is subject to many concurrent task demands and must therefore be particularly aware of workload management, including maintaining situation awareness, prioritizing tasks, and using autopilot effectively.

Most VLJs include much advanced cockpit technology intended to make the pilot's task simpler, but this equipment can actually increase the cognitive load on the pilot, as he or she must learn how to monitor the different systems, understand how the plane performs in different automation modes, and know how to locate resources quickly on a multi-function display. Because many potential VLJ pilots are experienced in flying planes with much lower maximum speeds, the increased speeds of VLJs compared to small propeller planes also increases the cognitive load because decisions must be made more quickly.

The National Business Aviation Administration identifies risks specific or crucial to VLJs, as opposed to corporate jets, due to the much lighter weight of the VLJs. These include wake turbulence encounters, convective weather encounters, wind shear, high-altitude upset, and mountain wave encounters. In addition, VLJs present flight patterns

somewhat unusual for air traffic controllers because they fly at relatively low altitude and are slower than commercial jets but faster than small aircraft such as a Cessna 140. Finally, several manufacturers have proposed safety devices to compensate for the possibility of mechanical failure while in the air, including the "whole-plane parachute" and rotor blades that can operate without power to provide a safe descent.

Production Difficulties

As the Eclipse 500 went into production, demand proved to be less than expected, making it impossible for the company to achieve economies of scale. Many of the expected purchasers were start-up air taxi operators such as the Florida air taxi service DayJet, who were creating a new (and unproven) business model based on this new type of airplane; for instance, DayJet placed orders for 1,400 planes, but eventually took delivery of only 28 (and ceased operations in 2008). Ultimately, Eclipse Aviation produced only 259 planes and filed for Chapter 11 bankruptcy in November 2008. Eclipse Aviation was bought by Eclipse Aerospace, a coalition led by Mason Holland, in August 2009, and in 2010 the new company announced it would deliver the first of a new model of plane, the Eclipse 550, to a customer by the fall of 2013.

Current Models

The Phenom 100, a twin-engine VLJ produced by Embraer, is the rare exception in the VLJ market—it was introduced on the market in July 2007 and remains in production today. The Honda Aircraft Company began production of the HondaJet, a twin-engine VLJ, in November 2012. Several other manufacturers have also announced or actually produced VLJ models, but most have since cancelled the line or gone out of business entirely. These include Adam Aircraft (the AdamJet), Aviation Technology Group (the Javelin), Avocet Aircraft (the ProJet), Piper Aircraft (the PiperJet), and Diamond Aircraft Industries (the D-Jet).

Aircraft Design

Aircraft design is an actively developing category of industrial design that encompasses mechanical, electrical, ergonomic, and chemical engineering. Aircraft design incorporates four broad areas of aeronautics development activity: (1) aerodynamics, (2) propulsion, (3) structures and materials, and (4) stability and control. Each is linked to the others, often in multifaceted and highly integrated ways.

Aerodynamics

Concern with airflow across surfaces and the principles of drag and lift are tied to the amount of power a given aircraft's engines need to deliver. The more aerodynamic the aircraft's surfaces are, the less drag is produced, and therefore the less work that must be done to provide thrust and lift. Less work means less fuel is consumed for a given flight maneuver, thereby allowing for longer flights from a given amount of fuel.

Maneuverability of the aircraft also derives from its aerodynamics. Flight surfaces must be designed with the inherent capacity for the desired stability and course alteration. Surfaces can also be designed with trim capability—for example, a wing can gain

added trim capabilities by virtue of an aileron, the bladelike hinged flight control surface typically installed in the trailing edge of the wing.

Within the domain of aerodynamics, designers must decide if the aircraft will be used primarily for subsonic or supersonic flight. This factor dictates the priority of building in various aerodynamic features. Some supersonic aircraft are designed with multiple transforming flight surfaces—for example, the "swing wing," which gives the pilot the ability to select wing configurations for optimal handling at different speeds. Among the more notable examples of such swing-wing aircraft historically is the F-111 fighter, manufactured by General Dynamics in the 1960s.

Engineers use wind tunnels and simulated wind tunnel programs to determine the optimal streamlining configuration for a given airfoil profile of a wing, fuselage, and so on. The ideal of streamlining is based on the path traced by a "massless particle" moving with the flow of wind around the aircraft mass.

Another area of design concentration is radar detection avoidance, or stealth, which can be achieved both by shaping aircraft surfaces to diffuse and deflect radio waves and by integrating low-reflectivity materials into surface fabrication.

Propulsion

Designers working in the domain of propulsion are concerned with power, reliability, durability, fuels, and the issue of exhaust and emissions. Engines must provide sufficient thrust for the aircraft to develop lift; they must operate effectively in various weather and atmospheric conditions and at different altitudes and aircraft attitudes; they must be designed with consideration of how to use available fuel mixtures to achieve a range of goals having to do with cost, noise, pollutants, exhaust visibility, and ease and stability of fuel handling. Decisions need to be made based on priorities that can include the amplitude and speed of power delivery versus fuel efficiency, power versus noise control, and power versus toxic exhaust.

In regard to piston engines, which are still widely important in general aviation, aircraft designers are making progress toward achieving high performance against the coming changes in fuel standards. Some of these new standards will be driven by raw cost factors, but others are driven by the concern over reducing or eliminating lead from aviation gasoline.

Plumes of colored dye flow over a 1/48-scale model of an F-18 fighter jet in a water tunnel used for determining optimal aircraft design at NASA's Dryden Flight Research Center.

Each alteration in fuel chemistry introduces changes in lubrication, corrosion, and horsepower—all vital components of propulsion design.

Jet engine designers, on the other hand, are hard pressed to devise new prototype and production models that will operate at reliably high standards while using completely new fuel mixtures. The driving force of this change is the environmental imperative to reduce the emission of greenhouse gases and various toxic substances such as sulfur dioxide and an array of chemical by-products of combustion of jet fuel additives. These additives are used to achieve a variety of important engine-preserving

tasks, such as corrosion reduction, thermal stabilization, static electricity dissipation, inhibition of fuel icing, and combating the growth of engine-fouling fungi and bacteria.

In contemporary aviation, the practices and mandates of such regulatory bodies as the U.S. Environmental Protection Agency (EPA) have become integral to prudent design, manufacturing, and operations standards and procedures. Rules from EPA regarding noise abatement; materials handling, recycling, and disposal; and engine exhaust limits, among others, must be taken into account during the conception and incorporation of aircraft design innovations.

The most widely used propulsion systems in aviation to date have featured propeller, turbo-propeller, rocket, and jet technology. Additional advances in propulsion may result from ongoing research and development in such categories as turbo-electric engines, which use very high-efficiency energy-source-to-fan transfer; rotating cylinder engines, which can help aircraft achieve vertical takeoff and landing; reaction engines (e.g., the Sabre) that combine conventional rocket technology with a mode that uses supercooled oxygen scooped from the atmosphere; and one or more energy sources that provide an alternative to traditional aviation gas (e.g., hydrogen fuel cells; plasma, nuclear, or solar photovoltaic systems).

Structures and Materials

The typical dichotomy in the domain of structures and materials is the tradeoff of strength and weight. Throughout the history of aircraft design, there have been periods when adding raw engine power was the default choice over the lightening of materials in order to gain performance. During other periods, most of the emphasis was on designing with technologically advanced materials such as aluminum and aluminum alloys, which could deliver great strength while greatly reducing the weight of the aircraft—thus cutting the need for more power.

The use of aluminum alloys was not simply a matter of substituting the material in place of steel; rather, the whole design and construction of the aircraft had to be reworked due to key metallurgical differences, such as the high sensitivity of aluminum to heat. However, by experimentation with various alloys and through heat tempering

and other treatments, engineers were able to make aluminum the material of choice in much of aircraft design.

In recent years, the use of composite materials has gained much attention and ever-increasing experimentation and application. Synthetic fibers, such as aramids, along with carbon fibers and other types of filament materials, can be manufactured into a variety of laminates or into a matrix that also combines ceramics, epoxies, polymers, and other ingredients. For more than four decades, materials science has made strides in fine-tuning mixtures of such ingredients and adjusting the combinative processes to develop end products that can greatly aid aircraft designers in replacing metal components with far lighter—and stronger—components.

Issues such as durability, conductivity, shear resistance, and many other performance factors of composite materials are now available for study via computer simulation, as a fairly robust database of experimentation has been compiled. Although not exhaustive, this simulation process can and does save aircraft designers valuable time in developing new applications that use these materials.

Design improvements also influence the economic practicality of various aircraft categories. For instance, far higher levels of reliability in engine construction have yielded flight durability and safety indices that provide for the broad-scale use of two-engine models in long-distance commercial jetliner fleets where formerly four-engine models were the accepted standard. At the other end of the size and scale spectrum, the development of “very light jet” (VLJ) aircraft in recent years was spurred more by market forces than by sheer technological advances; the niche for single-pilot private jets is one that has yet to be fully exploited.

Stability and Control

Increasingly, design for stability and control involves aircraft design engineers in the discipline of computer science and even artificial intelligence. This is the domain of aircraft design where the machine–human interface is most in evidence and where change and innovation are perhaps most vital. Ergonomic information is extremely useful in the design of cockpit gauges and other data displays, controls, and communications equipment, all of which must be integrated into the most

natural-feeling configuration possible. Not to be overlooked is the wealth of information gleaned from a century of human flight; designers have come a long way but still have to incorporate calculations of human pilots’ capacities, limits, and inevitable errors.

Redundancy of control is essential to design; it is just as important as accounting for various tolerance curves for stresses to the aerodynamics, engine and ancillary mechanical systems, and material structure of the aircraft. As new combinations of engines, fuels, trim systems, navigation, and structural components are designed and built, the basic handling features of a given aircraft are altered. It is critical to stay connected to human pilot feedback about such features, in addition to using the best computer simulations available. Both computer-generated engineering data and data derived through the use of flight simulators are invaluable to the design process.

Modular Design

Among the more futuristic transportation concepts that aircraft designers are beginning to work with in real time is the idea of modular design. At its most ambitious, this term refers to placing a passenger or group of passengers in a capsule that itself is transferred between modes of transport that can include road, rail, sea, and air. In some ways, this is akin to the development of container transport in the shipping of cargo.

For modular function of this type to be practically achieved in aircraft design, the passenger capsules must be able to affix to a fully independent flying wing type of aircraft, or to something similar that incorporates all essential aircraft components except the internal fuselage passenger cabin that has been customarily used. Theoretically, this type of modular transport, if standardized and widely adopted, could yield substantial savings in weight, materials, maintenance, loading and boarding time, terminal space, and intermodal handling.

Regulatory Issues

Although designers and engineers may prefer to develop new materials, components, and systems according to strictly mission-driven, mechanical-challenge, and pilot-preferred criteria, the reality of the modern flight environment imposes a range

of detailed and explicit airworthiness regulations and test protocols that must be met before new aircraft design prototypes can go into production. An example of a change in the regulatory structure advocated by aircraft owners, pilots, engineers, and mechanics is the Small Airplane Revitalization Act of 2013.

This legislation is intended to provide for faster, smarter testing and certification of new aircraft designs to augment safety and performance for VLJ and other prototypes and to streamline certification (and potentially reduce costs) of similar upgrades to existing aircraft. As adopted by the U.S. Federal Aviation Administration, the act holds the potential for a less cumbersome path to airworthiness certification for individuals and companies building and operating smaller, simpler aircraft to achieve better aviation metrics while also sustaining economic viability.

Aircraft Engine Emissions

Aircraft engine emissions have been the subject of technological innovation, commercial influence, environmental concern, and political and regulatory activism for decades. The various categories of aircraft engines yield different types of emissions, many of them directly harmful to human beings, others deleterious to the balance of atmospheric gases on which we depend. Two vectors are driving the changing nature of these engine emissions today: the technological drive for gains in energy efficiency, materials reduction, and power performance increases, and the environmental priority to cut greenhouse gas production and curtail the release of toxic agents.

Engine Types and Fuels

Thrust for forward propulsion and to develop lift in airplanes is provided by a range of engine systems designed around one of two main types: piston-driven propeller models, and reactive or jet engines. "Avgas" is the term used to refer to the aviation fuel used in piston engines. Jet engines burn jet fuel, a kerosene-based, low-volatility formula similar to diesel. Avgas—in contrast to automotive gasoline, where legislation reduced and ultimately removed lead—still includes lead in most formulations, specifically tetraethyl-lead, which has proven toxic qualities.

Jet fuels incorporate a vast array of additives that provide a range of important performance-enhancing and protective functions; but each of these may be suspect in terms of carcinogenic or other toxic outcomes.

Makeup of Emissions

With its lead content (used to increase octane levels and support better performance), avgas has been shown in various studies to be a factor in increased blood-lead levels in children residing near general aviation airports where many small aircraft take off

and land. There are some 20,000 such airports in the United States alone. The U.S. Environmental Protection Agency (EPA) has stated: “Emissions of lead from piston-engine aircraft using leaded avgas comprise approximately half of the national inventory of lead emitted to air.” The EPA has also noted as recently as 2010 that “serious health effects occur at much lower levels of lead in blood than previously identified” and that there is no known safe level of lead exposure.

Kerosene-based jet engine fuel, also called aviation turbine fuel, or ATF, embodies a group of fuel types that are chemically tuned to provide a range of performance standards for use in different atmospheric conditions and operational functions, as well as safety standards for storage, handling, and use. In recent decades, more adjustments to ATF have been tested and adopted with an eye to cutting air pollution and greenhouse gas emission. Synthetic fuel formulas, as well as biofuels, have been important in this regard. One example from among the key pollutants from ATF is benzopyrene, which is often found in smoke from other sources as well, such as cigarettes, forest fires, and petroleum combustion. This soot-carried chemical is absorbed through the skin and by inhalation; it is strongly linked to lung cancer and is highly suspect in many other cancers, as it has powerful mutagenic, or DNA-altering, qualities.

Both types of aircraft fuel emit hydrocarbon or greenhouse gases, in particular, carbon dioxide, nitrogen oxides, sulfur oxides, and water vapor. Besides atmospheric warming, these chemicals can also contribute to acid rain, ocean acidification, and health threats.

Standards and Monitoring

Airplane engines as air pollutant sources are monitored and regulated as a mobile source, along with sea vessels and land surface transport. Both the chemical makeup of the fuel used by these mobile sources and the design and quality of machining of the engines are main factors in emission type and volume. In particular, the European Organisation for the Safety of Air Navigation (EUROCONTROL) requires a form of aircraft performance model known as a Base of Aircraft Data (BADA) license, which also includes mandates on emissions assessment and provides licensees access to the Advanced Emission Model (AEM) computing system for purposes of calculating emissions.

Takeoff and landing (LTO) emissions are typically analyzed separately from non-LTO emissions. Likewise, there are varying guidelines based on altitude. Standards of the International Civil Aviation Organization (ICAO), for example, are used by EUROCONTROL for the calculation for activity below 3,000 feet of altitude, while its BADA standards guide the above-3,000-foot cycle. The AEM system is able to differentiate between six distinct LTO phases of operation: taxi out, take off, climb out, approach, landing, and taxi in.

Testing Alternatives

Strides have been made in recent years to develop alternative fuels whose chemical makeup will reduce the emission of greenhouse gases and toxic materials. These fuels have now been employed by both military and civil aviation well beyond early-prototype experimentation; some airlines now promote their use of biofuels on an everyday basis in at least part of their fleets as a marketing issue, for example. These include United Airlines, which has made much of its November 2011 application of an algae-based biofuel (blended with 60-percent regular jet fuel) on a commercial flight from Houston, Texas, to Chicago, thereby cutting hydrocarbon emissions. The fuel was manufactured by Solazyme Corporation in cooperation with the U.S. Navy.

Researchers are advocating that the Federal Aviation Administration (FAA), EUROCONTROL, and other agencies promote faster deployment of lower emission biofuels and synthetic fuels by subsidizing their use to some degree, and also by fostering higher efficiency engine design in general. Such analysts also propose incentivizing airport–airline partnerships to develop more effective operations to reduce emissions in both the LTO phase of flight—by updating air traffic and ground layout and flow—and in the non-LTO phase by better regional coordination toward more efficient flight paths and schedules.

and overhaul (MRO) is therefore one of great official scrutiny and necessary oversight. From original manufacture through years and even decades of flight service, every aircraft and its components must meet a certified set of standards that are monitored via regular specified inspections.

In the United States, the Federal Aviation Administration (FAA) designates as certified those aeronautical repair stations that meet the standards and inspection milestones administered through its Flight Standards Service. Additionally, when major design changes occur in civil aviation aircraft types or fleets, the FAA deploys its Aircraft Certification Service to test and approve the changes and to disseminate information updates pertaining to maintenance and safety.

Inspection Regime

The field of aviation safety—with its strict quantification and qualification regimes for mechanical fitness of aircraft; readiness of pilots, flight crews, and ground support staff; and intensive research into the causes and prevention of flight failures—has generated a robust structure of aircraft maintenance rules, metrics, reporting mandates, and enforcement mechanisms.

These regulations have evolved over the course of nearly 100 years, and the tangible results include such progress as the steadily declining incidence of fatal air accidents. The Continuous Airworthiness Maintenance Program (CAMP), established and administered under oversight of the FAA, features several levels of routine and detailed inspections. Each is done at a specified milestone based on a number of variables including flight hours, takeoff-and-landing cycles, or time elapsed since the initial operation of the aircraft.

The most fundamental and frequent type of inspection in civil aviation, commonly termed Check A, is typically accomplished overnight at an airport hangar or even at the terminal gate. A Check B CAMP inspection, usually done several times each year, tends to take an aircraft out of service for up to three days. The Check C routine is yet more involved, requiring considerable teardown of the aircraft; this necessitates an inactive period of up to two weeks and is repeated every 14 to 24 months. Finally, Check D, undergone about once in five years, entails nearly total teardown and can immobilize the aircraft for two months.

Aircraft Inspection and Maintenance

Maintenance is essential in keeping airworthiness levels high in airplanes and in their pilot support systems. The field of aircraft maintenance, repair,

Because these levels of aircraft inspection and overhaul necessitate major ground-based infrastructure investments, they must be taken into account during airport planning. They are characterized by capital-intensive fixed assets and high operating costs due to the need to employ highly skilled staff. Therefore, aircraft maintenance is a major component of both airline operations and airport administration.

Similar systems of inspection, component overhaul, and repair are in place outside the United States. For example, the European Aviation Safety Agency (EASA) operates a similar regime for civil aviation carriers doing business in the European Union.

Changing Market Conditions

Many major airlines operate their own in-house MRO facilities and operations. However, a plethora of stand-alone MRO companies provide service to every type of aircraft system, assembly, part, and repair situation, often with specialty maintenance lines that use the most advanced technology and that are staffed up to the highest skill set in the industry. Most airlines therefore find it convenient and cost-effective to contract a great proportion of their maintenance work. These contracts, along with the ever-changing dynamic of technological challenges and innovation in aircraft design and performance and the constant reviews and upgrades to the mandated regulatory inspection cycles, are the drivers of the MRO industry.

Due to swift and far-reaching changes in the regional airline business, MRO companies are undergoing a transition in customer base and in the economies of scale they must consider in order to remain competitive. Additionally, when major airlines are involved in increased subcontracting to regional carriers, those regionals must maintain additional aircraft models. Further, MRO companies that seek stronger bonds with national airline operators know they must add facilities in new locations.

Industry observers in general note that this focus on size, scope, and flexibility will not necessarily influence the basic metrics of a quality MRO provider—reliability, efficiency, and cost. However, the outsourcing of MRO functions is not without controversy. Among the more complex issues is the reality that MRO takes place in a global marketplace

In-house maintenance staff for All Nippon Airways (ANA) of Japan inspecting a jet engine at Tokyo Haneda Airport in April 2012. As of 2013, maintenance, repair, and overhaul (MRO) for jet turbine aviation was a \$65-billion industry worldwide.

affected by widely varying national and regional regulatory, inspection, and political structures. In the United States, the FAA undertook a major analysis and upgrade of its oversight of outsourced MRO following the 1996 crash of ValuJet Flight 592, an event that focused great scrutiny on the outsourcing of MRO. Critics of the FAA's efforts, such as spokespersons for the Professional Aviation Safety Specialists and the Aeronautical Repair Station Association, have stated that the FAA's inspection and documentation practices are in many cases largely redundant and therefore wasteful. In other cases, critics say, the FAA's policing lags behind or misses entirely the accomplishment of proper certification and timely monitoring of many subcontracted MRO operations.

Cooperation among some of the major global aviation regulatory bodies, such as the FAA and EASA, has increased in tandem with the expansion of MRO outsourcing—the goal being to standardize,

as much as possible, local MRO oversight and the resulting aviation safety and reliability. Complicating the achievement of such progress are issues like compliance with standing and in-negotiation labor agreements with union and nonunion workers, cost and tariff differentials between countries where MROs are based, and interagency regulatory regimes such as those between national aviation authorities and a host country's environmental, economic, and industrial-practices administrations.

Another change in the marketplace is the makeup of the civil aviation fleet itself. More than 6,000 jets and turboprop aircraft will retire from service over the next decade, according to industry projections—but the fleet will still grow by 3 percent annually. While carriers have been reducing, and continue to reduce, the number of various aircraft types flown, this pace of aircraft retirement portends a nearly unprecedented influx of new vehicles. It is both a challenge and a major opportunity for the MRO industry and its employees.

Scale of the Industry

According to a 2013 study by the Aeronautical Repair Station Association (ARSA), the global market for MRO services to the jet turbine sector of civil aviation is approximately \$65 billion and growing. The study pegs engine overhaul at some \$26 billion—the single largest segment—followed by component maintenance at about \$17 billion and heavy airframe maintenance at approximately \$13 billion. Line maintenance, which is most typical of a CAMP Check A service level, rings up to about \$10 billion.

The ARSA study finds that more than 4,000 MRO companies certified by the FAA are operating in the United States alone, accounting for about 196,000 employees engaged in the maintenance, repair, and overhaul of civil aviation aircraft. Most of these companies are small to medium in size; these firms account for about one-fifth of all employees. Another 45,000 MRO workers are directly employed by the air carriers to staff their in-house maintenance operations.

Additionally, there are more than 65,000 employees in the parts manufacturing and distribution sector of aviation, closely allied to the MRO field, who have many transferable skills and techniques. ARSA notes that these levels of economic activity and employment are signs of a robust and resilient

industry, especially when considering the economic struggles that began in 2008 in the United States.

Aircraft Maintenance Training Programs

Aircraft maintenance safety issues are particularly critical because they involve the safety of flight crew, passengers, and aircraft maintenance technicians. Errors in maintenance can cause damage or

destruction to aircraft and have a cost in people's lives and the profit of the company. The Federal Aviation Administration (FAA) through Advisory Circular (AC) 120-72 presents guidelines to develop maintenance resource management (MRM) training programs to improve aircraft maintenance safety.

Errors made by maintenance personnel are considered latent errors, meaning that they may lie hidden from view and undetected until sometime later during flight or after a number of flight hours. Some of the aircraft maintenance errors are using wrong parts; electrical wiring discrepancies; loose items left in aircraft; inadequate lubrication; access panels not secured; fuel/oil caps not secured; gear pins not removed before departure; parts damaged on installation; equipment not installed or missing; improper fault isolation, inspection, or testing; and preventative maintenance procedures overlooked.

Human conditions such as fatigue, complacency, and distraction are important because 80 percent of maintenance errors involve human factors. In an effort to improve safety by reducing human error, FAA AC 120-72 was created to provide background information on MRM. An MRM training program can provide the necessary training to assess and change behaviors to work more safely and to reduce human error by improving communication and safety in aircraft maintenance.

The "Dirty Dozen"

An important aspect of MRM is the "Dirty Dozen," or the 12 most common negative factors that influence a mechanic's performance. Recognizing the Dirty Dozen will identify the chain of events leading to an error and provide ideas on how to develop safety nets to prevent accidents. They were created by Gordon DuPont of Transport Canada after a string of maintenance-related accidents in the late 1980s and early 1990s. The first six are "lack of" communication, resources, assertiveness, awareness, teamwork, and knowledge. The second six are "abundance of" pressure, stress, norms, fatigue, distraction, and complacency in the workplace.

First is lack of proper communication, which will result in poor work quality, important information being misinterpreted, and higher levels of stress. Barriers to good communication include passive listening, no/poor feedback, nonstandard terms (acronyms), inappropriate communication

methods (verbal/nonverbal/written), vague or ambiguous information, and late information. These barriers exist between technicians, supervisor to technician, pilot to technician, and different maintenance departments. Safety nets that can be used to prevent problems are use of checklists and worksheets, proper "turn overs" to other technicians to complete the work, and an attitude of never assuming anything.

Second is the lack of resources, which includes technical manuals, parts and materials, tools, proper lighting, shelter from the elements, heat or cool temperatures, technical support (engineering), people, time, and ground support equipment. Resource safety nets involve ordering all necessary parts in advance and verifying they are on hand before starting a maintenance job, or arranging for a loan of parts and equipment when needed. Standards must always be maintained, and when in doubt, the aircraft must be declared unairworthy or be grounded.

Third is lack of assertiveness. Aircraft technicians need to be assertive when something is wrong to ensure a problem is not overlooked. A three-step assertiveness method is to be accurate, bold, and concise. Barriers to assertiveness may involve rank or position differences in authority, peer pressure, and a lack of confidence due to lack of knowledge or experience. Assertiveness safety nets involve recording all work in the aircraft log book and signing only for what is serviceable. When in doubt, it should be written up in the book, and technicians should refuse to compromise their standards.

Fourth is the lack of awareness of important job-related conditions and events. This often occurs when there is insufficient communication, fatigue or stress, task overload or underload, and degraded operating conditions. Maintenance technicians may fail to think fully about the consequences of their work. The safety nets are to check to see if the work will conflict with an existing modification or repair by being aware of technical data revisions, to ask others to check their work, and to be aware of their surroundings.

Fifth is a lack of teamwork because people are not working together properly. Safety nets are for the team to discuss the what, who, and how a job is to be accomplished and to verify that everyone understands and agrees with the plan before beginning the job.

Sixth is a lack of knowledge, which can cause an error in judgment. The safety nets are to get training on the task, use current technical manuals, and when in doubt, ask for help.

The seventh item begins the concern for an abundance of pressure. Pressure is a form of stress and usually is caused by a lack of time, resources, or people to complete a task. The safety nets are to be sure the pressure is not self-induced, communicate any concerns, ask for help, and when necessary, just say no.

Eighth is an abundance of stress, which can result from personal issues, seeking approval from the boss, concerns with the weather, and having difficulty with the repair. Safety nets involve workers being aware of how stress can affect their work, pausing to evaluate the situation rationally, deciding on the best plan, resting when needed, talking about the problem with someone, having a coworker check your work, and eating properly and exercising regularly.

Ninth is an abundance of norms. These unwritten rules become pressures on a group. Ineffective norms are detrimental to organizational goals and they reduce effectiveness. Safety nets are to always use written instructions, or have them changed, and to be aware that norms do not make it right.

Tenth is an abundance of fatigue, which reduces the effectiveness of a person's ability to work. Fatigue is caused by loud noise, excessive vibration, improper lighting, change in shift hours, long work hours, lack of sleep, stress and exertion, and large temperature changes. Symptoms of fatigue are often not recognized until an error or accident occurs. Safety nets are to get enough sleep and exercise often, look for symptoms of fatigue in oneself and others, avoid doing complex tasks when tired, and have a coworker or supervisor check your work.

Eleventh is distractions, a common occurrence, yet if they occur during a critical phase they can be disastrous. Technicians should try to complete the task or unfasten the connection, mark the work as incomplete, double-check the work or have a coworker check it, go back over the last three steps when returning to an incomplete job, and always use a checklist and technical data.

The last performance factor is an abundance of complacency. Due to the repetitive nature of maintenance, a degradation of vigilance occurs. Safety nets exist to train the technician to look for and

expect to find fault and never to sign for anything the technician did not do or see done.

Conclusion

Errors can be made by anyone, including experienced technicians and in organizations previously thought to be safe. Aviation maintenance safety can improve with an aggressive MRM program that includes recognizing the symptoms of the Dirty Dozen.

Aircraft Manufacturing

Many people had flown aircraft such as balloons that were lighter than air, but on December 17, 1903, Orville Wright made the first successful flight in an airplane that was heavier than air. It was a controlled flight of a plane powered by a small internal combustion engine. The flight lasted only 12 seconds and the plane traveled just less than 130 feet (40 meters) at Kitty Hawk, North Carolina.

Others had attempted heavier-than-air flight, but the Wright brothers invented aircraft controls that made fixed-wing flight possible. The focus of their research was on developing a reliable method of pilot control for steering the airplane and maintaining its equilibrium through the use of a three-axis control of the rotations of a craft's roll, pitch, and yaw. The roll, pitch, and yaw are similar to those of ships, which also must be controlled as they move

Wing assembly for the Boeing 747-8, an updated and extended version of the 747, in July 2009. The Boeing aircraft manufacturing company originated when Seattle lumberman William Boeing built a seaplane with Navy lieutenant Conrad Westervelt in 1914. Boeing then began the Pacific Aero Products Company, which eventually became the Boeing Airplane Company.

dynamically through the medium of a liquid fluid rather than a gaseous fluid.

Their bicycle shop in Dayton, Ohio, was where Wilbur and Orville Wright honed their mechanical skills on printing presses, bicycles, machinery of various kinds, and various motors. They came to believe that the solution to flight problems, like that of bicycles, was the establishment of stability in motion. They built a wind tunnel to refine their knowledge of flight dynamics. Developing their piloting skills with gliders between 1900 and 1903 at Kitty Hawk, they also made Charles Edward Taylor, a bicycle shop employee, a part of their team. Taylor built the engine used by the Wright brothers on their first flight.

Between 1903 and 1908 the Wright brothers continued to improve their airplanes as they sought to gain patents and contracts to build planes. On May 14, 1908, Wilbur flew the Wright Flier III with young mechanic Charles Furnas (1880–1941) as his passenger.

Ready to begin selling their invention, Wilbur went to France to quell intense skepticism that they had not made heavier-than-air flights. Flights in the Model A Flyer were very successful as Wilbur made a figure eight and circles and conducted other challenging demonstrations of his skills as a pilot in control of his aircraft. French aviation enthusiasts were amazed and flocked by the thousands to the airfield to see the show. Wilbur's flights also attracted British and German interest. The flights also gained them a test demonstration by Orville for the U.S. Army that was also successful.

While in France, Wilbur flew Edith Berg, the wife of their European business agent, as the first woman passenger on October 7, 1908. She was one of many who were passengers with him that autumn. However, tragedy struck on September 17, 1908, when army lieutenant Thomas Selfridge, a passenger on a test flight with Orville, was fatally injured. The crash was caused by a propeller that

split into pieces. It left Orville badly injured and in a long hospital recovery.

In July 1909 Orville and Wilbur delivered to the U.S. Army a two-seat airplane that could fly for an hour at an average speed of 40 miles per hour (64 kilometers per hour) and land undamaged. The plane was delivered after a series of proving flights. Their payment included a bonus for delivering a plane that could fly faster than specified in the military contract.

The Wright brothers were issued a patent on May 22, 1906, for new and useful improvements in flying machines. However, by 1908 many others were reengineering the invention or were making improvements to other ideas of the brothers. A flight by Glenn Curtiss using ailerons was viewed as not covered by the Wright brothers' patent. This disagreement led to a patent-infringement lawsuit war between the Wright brothers and companies in America and Europe. In January 1914, a federal appeals court ruled in favor of the Wrights and against the Curtiss Company.

With World War I under way and a demand for airplanes mounting, Orville sold the Wright Company in 1915. The federal government then promoted a cross-licensing agreement between aircraft manufacturers. In 1929 the Wright-Martin and the Curtiss Aeroplane companies merged to form the Curtiss-Wright Company.

World War I and subsequent wars in the 20th century stimulated technological inventions in the aircraft industry. During peacetime periods, innovations and experimental ideas were developed by the numerous civilian companies, in many cases as they converted from wartime production to civilian production. In 1908 Edson Gallaudet organized an aircraft engineering center, which became the ancestor of the General Dynamics Corporation. In 1910 he opened the Gallaudet Engineering Company, and he reorganized it in 1917 as the Gallaudet Aircraft Corporation. In 1918 it began production of the Curtiss floatplanes. It was sold in 1923 to the newly formed Consolidated Aircraft Company.

The Burgess Company began manufacturing Wright aircraft in 1911. It built modifications of Wright license agreements by adding pontoons to some Wright planes. In 1913 it delivered to the U.S. military a tractor biplane and later a Burgess seaplane. In 1916 it merged with the Curtiss Aeroplane and Motor Company.

The Thomas Brothers Company began manufacturing biplanes for the Royal Naval Air Service in 1914 in Ithaca, New York, and in Bath, England. In 1917 they merged with the Morse Chain Company to form the Thomas-Morse Aircraft Corporation. Training numerous American and Canadian pilots, they also developed new models of airplanes. The expertise in manufacturing fighter aircraft was turned to racing planes and training aircraft.

In 1910, Columbia University granted the first aeronautical engineering degree to Grover Loening. He began working with the Wright Company in 1913 but quickly grew disenchanted with its management. He then became the chief aeronautical engineer for the U.S. Army Signal Corps in San Diego, California. In 1915 he helped organize the Sturtevant Aircraft Company, which focused on naval aviation. The first Sturtevant aircraft was the Kitten, which was intended as a scout plane but developed into the M-8, one of the first American fighter planes.

In 1914 the Boland Aeroplane Company was renamed the Aeromarine Plane and Motor Company. It manufactured more than 300 military planes in New Jersey during World War I. It later improved flying-boat aircraft.

Glenn Martin built his first successful airplane in 1909. In 1911 he founded the Glenn L. Martin Company, which built the Model TT tractor-engineer trainer for the U.S. Signal Corps. In 1915 Martin hired Donald Douglas as an engineer. In 1916 the Martin Company merged with the Wright Company to form the Wright-Martin Company. However, displeased with the results, Martin moved to Ohio in 1917 where he formed a second Martin Company. He was joined by Douglas. With a contract from the U.S. Army, they manufactured 10 successful bomber planes.

In 1912, Allan and Malcolm Loughead organized the Alco Hydro-Aeroplane Company. In 1916 they formed the Loughead Aircraft Manufacturing Company which, in 1918, rolled out the 10-passenger F-1 seaplane. However, the demand crashed at the end of World War I. The company's other work, subcontracting and building Curtiss HS-2L flying boats, did not prevent the bankruptcy of Loughead Aircraft in 1921.

In 1914 William Boeing, a successful Seattle lumberman, built a seaplane, the B&W, with Navy lieutenant Conrad Westervelt. Boeing then organized an aircraft manufacturing company, the Pacific Aero

Products Company. The name was later changed to the Boeing Airplane Company.

The L-W-F Company, founded in 1915, developed a laminated wood fuselage. It also developed the monocoque fuselage, which was a major improvement over earlier fuselages.

Ryan Aviation built the Spirit of St. Louis to Charles Lindbergh's specifications in the 1920s. The company's founder, T. C. Ryan, went on to develop other aviation products, and the company was eventually merged with other companies. Historically, the pattern has been for companies to absorb one another, but for new companies to then emerge. Military contracts create wartime feasts and peacetime famines in the world of aircraft manufacture.

Most of the early civilian aviation companies disappeared. Some merged to become the giants of later decades. During the 1930s and 1940s, several new aviation companies entered the market. The Grumman Aircraft Engineering Corporation was founded in 1929. It was acquired by Northrop Corporation to become Northrop Grumman in 1994.

Modern civilian-aviation airliners developed rapidly after World War II as engineering advances in bombers such as the B-29 allowed for long-distance flight. By the 1960s, air travel was replacing railroad and steamship travel. The Boeing 747 was introduced in 1970. New jetliners were developed thereafter by Boeing (757 and 676), by McDonnell Douglas (MD-11), by Lockheed (L-1011-500 Tristar), and by other companies. The Airbus and Concorde were superliners but were eventually replaced by newer models. As aviation markets have fluctuated the pattern of corporate takeovers has continued, as has development of new models of planes. The terrorist attacks using hijacked airliners on September 11, 2001, harmed the business of commercial airlines. It also hurt sales for new airplanes, causing some business takeovers. However, airliner development has continued. One plane that attracted wide public interest was the Boeing 787 Dreamliner, rolled out in 2007, which was capable of carrying several hundred passengers. It has experienced fires from its lithium batteries, a problem that had not been solved by November 2013.

Attempts at improving airplanes have been constant since the era of the Wright brothers. At first all aircraft were civilian. The general-aviation side (small private planes) of civilian aviation has

included those companies that are able to survive by supplying the many markets including racing planes, seaplanes, cargo transports, corporate jets, bush planes, large passenger planes, and other kinds of aircraft. New private aircraft (e.g., the Learjet, the Beech Bonanza D35, the Cessna 1728 Skyhawk, the Cessna 340, the Piper PA-46-350P, the Rutan Model 33, and many other models, including non-American aircraft [e.g., the English Slingsby T.67C Firefly]) continue to come to the general aviation market to supply growing flying interests. Many are using new light composite materials as well as traditional lightweight metals.

Aviation advances in light aircraft, drones, balloons, and gliders have continued to grow, as has civilian interest in the commercial development of rockets for space travel.

Military planes have continued to advance with long-range bombers such as the Northrop stealth B-2. Transport plane development has continued beyond Lockheed's C-5 cargo plane with tactical transports. Fighter planes continue to advance with application of military spending. The research from such national security investments eventually aids civilian aviation.

Aircraft Propulsion, New Technologies of

The common public perception is that the National Aeronautics and Space Administration (NASA) is an organization dedicated primarily to travel in outer space. However, it is likely that the organization will play an integral part in the development of the next three generations of passenger aeronautics. This influence is coming from NASA's N+3 program. This program is directed toward solving problems of environmental and social impact, including airplane emissions, sound pollution caused by passenger jets, and finding ways to utilize regional airports, which are often underused. The means to achieve these goals are being pursued by multiple teams. These teams are backed by private interests and have been granted funding by NASA to address individual aspects of the N+3 program by 2025.

Explaining N+3 Goals

In the early 2000s, NASA developed a set of research objectives known as the N+3 goals. These goals are directed toward developing the next three generations of aircraft, thus the name N+3. The N+3 goals are based on the three core objectives of reducing energy consumption, reducing noise associated with both subsonic and supersonic flight, and reducing toxic emissions. These goals were established to guide funding to organizations interested in developing the technologies that would usher in the next generation of aeronautic propulsion.

The name N+3 denotes that the goals will direct the development of propulsion technologies through the next three generations of flight technology. These goals are set in three tiers: N+1, N+2, and N+3. The N+1 goals are set to be met by the participants in the project by 2015. By this time, the participants are working to meet goals in sound reduction, toxic emissions, and fuel efficiency. Additionally, participants are expected to meet certain field length performance requirements, which require vehicles to be able to land and take off using shorter distances than possible with conventional aircraft. Furthermore, participants are expected to have their prototypes emit 60 percent less nitrogen oxide emissions and to improve their fuel burn by 33 percent. In 2015, NASA expects participant to develop craft that are 32 decibels quieter than their

2008 counterparts. Field length performance is also expected to be improved by 33 percent. Goals related to sound reduction and field length are being set primarily so that airports can be located closer to city centers.

The N+2 goals are due to be met by 2020. At that point, participants are expected to have reduced engine sound output by at least 42 decibels. Additionally, nitrogen oxide emissions are to be reduced by 75 percent, aircraft burn is to be improved by 50 percent, and field length performance is to be improved by 50 percent.

The final set of N+3 goals are to be met by 2025. By this time, engine noise is to be reduced by 71 decibels. Nitrogen oxide emissions are to be improved by better than 75 percent, and aircraft fuel burn must be improved by better than 70 percent. Finally, field length performance is expected to exploit metroplex concepts (which individuals to commute between cities in close proximity, thus having the effect of creating one large city.) by 2025; these concepts have been recognized by both NASA and the Federal Aviation Agency (FAA). By exploiting metroplex concepts, these vehicles will be able to contribute to utilization of closely spaced airports, increase arrivals and departures, and navigate congested metropolitan areas.

How the Goals Will Be Achieved

After establishing goals, the next step is to determine how they will be met. N+3 goals will likely be met in one of five ways. Participants are anticipated to meet goals either structurally by altering the design or by utilizing advanced materials. When structurally altering the design of the craft, changes may be made to reduce the weight of the secondary structure (those parts that if damaged do not directly impair the flight of the craft). Structural changes can also be made to alleviate drag issues by installing high-aspect-ratio wings, which tend to be very long and narrow and serve to grant a greater amount of lift. N+3 goals can also be met by incorporating advanced materials into the design of the craft. This may be done by including advanced structural materials and advanced engine materials into the design.

N+3 Participants

On October 6, 2008, NASA awarded research contracts totalling \$12.4 million to six private teams

that agreed to study advanced concepts for subsonic and supersonic commercial transport that could enter service in 25 to 30 years under the terms of the N+3 goals. The six teams were drawn from five private U.S. entities. The Northrop Grumman Systems Corporation specializes in unmanned drones, cybersecurity, and security systems. In working toward its N+3 goals, Northrop Grumman is focusing on environmental issues, including noise footprints and improving runway stopping distances. The Massachusetts Institute of Technology (MIT) is a private research university located in Cambridge, Massachusetts; it consists of five schools and one college. MIT is developing a subsonic fixed-wing transport aircraft. This craft will likely utilize a liquid natural gas fueled, multiple engine propulsion system. Lockheed Martin Corporation is an aerospace company with global interests and a long history of working with the U.S. government for military and civilian purposes.

Lockheed Martin is developing environmentally friendly supersonic airframes, and technologies that will reduce airport noise and emissions for the N+3 project. GE Aviation is a subsidiary of General Electric. This subsidiary is one of the top aircraft engine suppliers for the aviation industry. GE Aviation is working on technologies that will reduce environmental impact as much as possible and maximize existing regional and suburban airports toward this end as much as possible. The Boeing Company is a U.S. aircraft designer and builder serving multinational aerospace and has a long history of defense contracting. Boeing is hosting two teams. These teams are focusing on vehicle sizing, environmental conformity, risk mitigation, noise reduction, emissions, takeoff length, fuel use, and energy utilization.

The majority of effort surrounding the N+3 project focuses on developing various aspects of either superconducting electric aircraft propulsion or hybrid electric aircraft propulsion. On this topic, superconducting electric aircraft propulsion is critical because N+3 craft require extremely efficient engines in terms of mass-to-power generated. This is because engineers seek to get the greatest amount of power for the mass of the engine. Most efforts are focusing on developing turboelectric propulsion; however, efforts are made in exploring other hybrid electric technologies and other types of propulsion.

A rendering of the Subsonic Ultra Green Aircraft Research (SUGAR) Volt aircraft concept submitted to NASA by a Boeing research team in April 2010. The twin-engine plane would use hybrid propulsion combining gas turbine and battery technology.

Turboelectric research is by far the propulsion type of greatest interest to N+3 projects. Turboelectric engines are similar to conventional jet engines in that they convert mechanical energy generated by turning a fan (i.e., turbine) into electric energy to power the craft. Turboelectric propulsion systems differ from conventional jet engines in that instead of relying on two to four large fans affixed to their power source, they utilize many smaller engines spread over the entire wing area. This has several effects: in terms of power generation, it serves to provide a larger fan surface area, thus creating a greater amount of electricity.

In regard to structural design, most proposed turboelectric craft should be able to approach runways at steeper angles with less noise and require shorter runways. These feats are possible because the multiple turbine design makes engines more effective. Additionally, since engines are mounted on top of the plane, sound is dampened as lift is reduced. This sound reduction could allow for a greater number of nighttime takeoffs and airports could be located closer to city centers. Furthermore, the need for less runway space allows for

greater utilization of regional airports and would further encourage the construction of airports in highly developed city centers. These features could be incorporated into craft featuring other types of propulsion, but they are most prominently featured in turboelectric designs.

Hybrid Electric Technologies

Although turboelectric technologies have been favored by N+3 researchers, they are still heavily dependent on liquid fossil fuels. Hybrid electric technologies, which are within the scope of the N+3 goals, seek to either minimize or eliminate dependence on these fuels. These types of aeronautic propulsion systems were flown as early as 1957. However, this type of experimentation has seen great resurgence in recent years, in part due to the N+3 goals. Electric double-layer capacitors are a type of next-generation high-power battery. These super batteries may take the form of fuel cells or solar cells. Double-layer capacitors may also be paired with power-beaming technologies, which transmit electrical energy from a power source to its goal without conductors; good candidates for power beaming include microwaves or lasers. The benefits of electric-based propulsion systems include the safety gained by excluding liquid fuel, fuel efficiency, and reduction or elimination of toxic or global warming-contributing gases..

Airline Deregulation Act of 1978

Much of the history of transportation in the United States has been characterized by government regulation, which has been considered necessary since the heyday of the railroad industry. In 1936, Congress extended the Railway Labor Act of 1926 so that airline labor issues were brought under that same umbrella of government oversight. In 1938, the Civil Aeronautics Authority (CAA), which became the Civil Aeronautics Board (CAB), was assigned responsibility for approving airline routes and rates and for certifying carriers within designated markets.

By the 1970s, however, there was considerable support for deregulating the transportation sector. The first major move in the route toward deregulation began with bipartisan support that resulted in the passage of the Airline Deregulation Act of 1978 (S. 2493). The act was signed into law (P.L. 95-504) by President Jimmy Carter on October 24, 1978. Upon signing it, Carter stated that the act would accomplish the twin purposes of fighting inflation and lowering the price of airfares so that they would be more affordable for the average American.

Airline officials were elated that deregulation was ushering in a period in which they could establish or eliminate routes according to the dictates of the market, allowing competition to flourish without government interference. Even before the Airline Deregulation Act of 1978 was signed into law, Alfred Kahn, the chairman of the CAB, had been overseeing the early stages of deregulation, working toward the ultimate goals of amassing higher profits for airlines while reducing fares by as much as 50 percent. The Airline Deregulation Act was

not intended to compromise airline safety, which continued to be regulated by the Federal Aviation Administration (FAA).

Background

In 1926, Congress passed the Air Commerce Act, which gave the Department of Commerce the authority to regulate the operations and safety of airlines. In 1938, the Civil Aeronautics Authority, the forerunner of the CAB, was established to concentrate those functions within a single agency. The CAA comprised five members who worked with the agency's administrator to carry out the agency's mission. Safety oversight was assigned to the three members of the Air Safety Board. By the late 1930s, there was mounting concern over airline safety issues, the financial health of airlines, and complaints about existing inequities within the transportation sector. In 1940, under President Franklin D. Roosevelt, the Civil Aeronautics Authority became the Civil Aeronautics Board, and the CAB took on the responsibilities of both the CAA and the Air Safety Board. The CAB continued to exercise the authority to limit the number of airlines operating in the United States. In 1938, there were 16 so-called trunk airlines providing air service.

By 1974, the number of trunk airlines had dropped to 10, even though the CAB had received 79 applications from airline companies desiring to open new businesses. Two years later, William T. Coleman, Jr., the secretary of transportation, and Senator Ted Kennedy (D-MA) cowrote the Air Transportation Regulatory Reform Act of 1976, which attempted to initiate the process of deregulating the airlines. However, the bill failed to garner sufficient support for passage. In 1978, with the support of the Carter administration, Senator Howard W. Cannon (D-NV) introduced a new airline deregulation bill, and the Senate passed the Airline Deregulation Act of 1978 by a vote of 82–4. Due to considerable bipartisan support, the House also passed the bill by an overwhelming majority (356–6).

Public Law 95-504

The Airline Deregulation Act of 1978 (P.L. 95-504) provided for government regulation of airline activities to be phased out over the following years. As of December 31, 1981, CAB control over airline routes was essentially abolished. The following month, airlines were granted control over interstate and

overseas routes according to an automatic entry system. Airlines gained control of their own rate plans on January 1, 1983. The bill established 1985 as the date by which the Civil Aeronautics Board was likely to be eliminated. Upon elimination, any federal power that still resided with the board was to be distributed among the Department of Justice, the Department of Transportation, and the U.S. Postal Service.

Unless considered a predatory action under CAB guidelines, airlines were allowed to decrease fares up to 50 percent. In order for a route to be considered active, an airline was required to provide air service five days a week for 13 weeks during a 26-week period. By the fall of 1978, 1,295 routes had been declared dormant under this provision. Airlines responded by filing papers to have them reinstated. The bill also included protections for smaller communities by guaranteeing service for a decade after the deregulation process began. Certain stipulations continued to govern procedures for labor disputes. Airline officials were required to place strike-related funds in the Mutual Aid Pact. No operating costs could be transferred from the fund for 30 days, but 60 percent of operating expenses could be used during a period that began 30 days after the strike was initiated and ended eight weeks later. Any carrier experiencing a strike was required to submit to arbitration. In cases of bankruptcies and major financial losses that resulted from deregulation, nonmanagement employees were to be protected for 10 years through guaranteed salary parity.

Impact

In 1978, when the Airline Deregulation Act cleared Congress, there were 36 certified passenger carriers in the United States. Within six years, that number had climbed to 123 carriers. By February 1979, the airlines had created 150 new service routes, and plans for other routes were under way. Even though deregulation was designed to spur the economy, the intense competition that accompanied deregulation spelled financial disaster for many airlines. According to *Airlines for America*, which lists bankruptcies and service cessations for all airlines located in the United States and in American territories, two airlines filed for Chapter 11 bankruptcy protection in 1979. The number of filings climbed in the 1980s, totaling 87 for the decade. The number of Chapter 11 filings dropped to 44 in the 1990s as the result of

an improved economy but rose to 54 between 2000 and 2012 as the United States experienced a major recession. Between 2001 and 2005, airlines reported almost \$28 billion in operating losses. Bankruptcies affected even large airlines, and both Pan-Am and Eastern folded. When airlines declared Chapter 11, all labor contracts and pension plans were voided. Thus, employees often faced financial disaster on both a personal and a professional level. Some airlines fought to survive by merging with other airlines. In 1987, only 74 of 245 airlines certified since the passage of the Airline Deregulation Act remained in operation. Nine major airlines continued to control 90 percent of the market, according to a report issued by Airline Economics, Inc.

As deregulation of the airlines was put into practice, airlines were ostensibly free to establish new routes and eliminate those that were not deemed profitable. However, some exceptions remained in place. One of those exceptions arose from the Wright Amendment, pushed through Congress by Texas Democrat Jim Wright. The Wright Amendment retained limits on certain airlines in order to protect them from major competitors. For instance, Love Field, which served the Dallas/Fort Worth area, was banned from accommodating flights destined for cities outside Texas except for those traveling to Arkansas, Louisiana, New Mexico, and Oklahoma. This lack of competition resulted in passengers in Texas paying as much as 75 percent more for airplane tickets than did passengers in neighboring states.

Other airlines were limited by the practice of “slots,” which was designed to limit congestion at airports by restricting the number of takeoffs and landings permissible within a single hour. The practice of slots also increased airfare because the price of tickets was increased in response to delays imposed on other aircraft waiting to take off. A third limit on airlines concerned perimeter rules, which limited the length of flights going to or coming from New York’s LaGuardia Airport and Ronald Reagan Washington National Airport in Washington, D.C., by limiting the miles flown to and from those airports to 1,500 and 1,250 miles, respectively. Application of perimeter rules also raised the price of airline tickets for passengers in those areas.

While passengers were delighted with the decrease in the price of airline tickets, many were inconvenienced by the decision to create the

“hub-and-spoke” systems that routed passengers to designated airports. Passengers also had major gripes about bad service at most airlines. Since airlines could garner higher profits from routes to major cities, passengers also complained that smaller communities were not being adequately served under deregulation. Indeed, between 1978 and 1984, the number of communities served by airline routes declined from 632 to 541. The general public blamed the federal government for increased congestion at existing airports because of the lack of federal assistance for building new airports. Airline employees also complained about the changes wrought by deregulation. With pilots and crews working longer hours and equipment not always in proper repair, the number of near-midair collisions increased. When 13,000 stressed air traffic controllers initiated a strike in 1981, demanding higher wages and a shorter workweek, President Ronald Reagan summarily fired them and issued a lifetime ban that prevented all striking air traffic controllers from returning to their jobs in the future.

Conclusion

Overall, deregulation of the airlines has been considered successful, and Jimmy Carter has earned praise for his role in initiating the process. Under subsequent presidents, deregulation spread to the railroads and the trucking industry. In 2006, within the context of discussions about reregulating the airline industry, the Government Accounting Office (GAO) issued a report on the impact of airline deregulation. The report stated that industry capacity and passenger traffic had tripled since the passage of the Airline Deregulation Act of 1978. The GAO determined that between 1980 and 2005, airfares had fallen by nearly 40 percent. Airlines had become more competitive since deregulation, but service was deemed to have improved only slightly. The conclusion of the GAO was that reregulating the industry would likely reverse benefits gained by deregulation.

processes that increased revenues by offering different prices to different segments of customers.

Market Segmentation

Traditionally, revenue management in the airline industry focused on segmenting business and leisure travelers. Leisure travelers typically book further in advance and are price sensitive, whereas business passengers typically book later and are less price sensitive. By segmenting these customers, carriers are able to charge passengers a price that is closer to the amount that they are willing to pay. The market can be segmented by creating different types of round-trip fare products that are tied to various fare conditions and ticket restrictions. The lowest priced fare products are often tied to advance purchase restrictions, length-of-stay requirements, and/or Saturday-night-stay requirements. For example, many of the lowest fares require a passenger to book at least 14 days in advance of flight departure and require the trip length to be longer than one day. This effectively creates a fare product that would be unattractive to business passengers. Most of the lowest priced fare products are also nonrefundable. In order to purchase a more flexible, refundable ticket (which is more attractive to business customers), the customer must purchase a more expensive ticket.

Over time, however, new low-cost carriers (LCCs) began entering the market to compete with the older legacy carriers. LCCs have different business models and approach ticket pricing differently than legacy carriers. LCCs focus on keeping operating costs low so that they can offer lower fares than legacy carriers. LCCs have simple pricing structures that use one-way pricing instead of round-trip pricing, which removes length-of-stay and Saturday-night-stay restrictions. The introduction of these simplified pricing approaches has made it more challenging for legacy carriers to charge different prices for business and leisure customers, which in turn has lowered their revenues. Both legacy and LCCs have embraced ancillary fees as a way to increase their revenues.

Pricing and Ancillary Revenue Trends

Since deregulation, average airfares have decreased. For example, after adjusting for inflation, the Bureau of Transportation Statistics (BTS) finds that average airfares decreased by 15.6 percent between 1995 and 2011. Although there are many reasons why airfares have decreased since deregulation, one main factor

Airline Fares

Before the U.S. airline industry was deregulated in 1978, the Civil Aeronautics Board controlled fares, routes, and schedules. During the regulation era, all passengers in the same class paid the same price, or fare, to fly on a route. After deregulation, carriers were able to make decisions about how much to charge, where to fly, and when to fly. The practice of offering one price to all customers changed, and carriers began implementing revenue management

is the increased market penetration of LCCs, which has led to increased fare competition. Additionally, the increased use of the Internet has led to pricing transparency. Online travel agencies such as Expedia, Orbitz, and Travelocity allow customers to quickly search the prices of multiple airlines across multiple departure dates. As a result, some studies have found that 60 percent of leisure travelers report that they purchase the lowest fare they can find. The need for carriers to remain price competitive has resulted in the development of pricing decision support systems. These systems help airlines identify when their competitors' fares change and provide recommendations on how the airline should respond to these fare changes. Airlines file fares with fare distributors such as the Airline Tariff Publishing Company (ATPCo). Airlines update their fares up to three times a day and submit over 1 million fare changes daily through ATPCo.

To remain profitable, airlines introduced new ancillary fees for services that used to be bundled into the base price of a ticket, including fees for checked baggage and seat reservations. In addition, fees for existing services increased, including fees for checking pets, redeeming mileage award tickets, and exchanging tickets. According to the BTS, from 2007 to 2011 ancillary revenues reported by U.S. carriers with operating revenues over \$20 million increased nearly threefold, from \$3.6 billion to \$9.8 billion. Increased revenues from ancillary revenue streams have also been reported worldwide.

Future of Airline Pricing

Today an increasing number of bookings are being made online, which presents an opportunity to use detailed search and purchase information to learn about customer preferences and to design products and services that better align with their preferences. For example, when a customer conducts a search on an airline's Web site, clickstream data is collected that shows what the customer searched for and whether he/she booked a ticket. Analyzing this clickstream data could give airlines a better understanding of how passengers purchase tickets. This may eventually lead to more customized pricing.

Airline Flight Reservation and Ticketing Systems

Today's airlines use sophisticated software to manage passenger reservations, ticket records, and the fees and tariffs charged by airports and state and federal agencies. Due to the complexity of managing reservations, flight schedules, and layovers, airlines

were early adopters of computerized systems. The first such system, the Reservisor, was developed for American Airlines in 1946, at a time when the few computers that did exist were largely purpose-built for use by government agencies and research institutions. The Reservisor was an automated booking system, but these early computers required a team of human operators who coordinated with another staffer who answered the telephone to communicate with travel agents. Nevertheless, it proved popular and similar systems were adopted by other airlines and by hotel chains.

American Airlines continued to work on its system, replacing card files with a magnetic drum with the introduction of the Magnetronic Reservisor, and meetings with IBM in the early 1950s culminated in IBM's proposal to develop an "electronic brain" to tackle the task of managing flight reservations. The arrangement between American and IBM was formalized in 1957. IBM's work on the matter was based on the company's previous work for the U.S. Air Force, in which an early online system had been developed to coordinate communication between radar sites and fighter aircraft. The same type of teleprinters used in the Air Force project could be used in American Airlines ticketing offices, allowing elements of an airline flight reservation system to communicate with each other without the need for human operators on the telephone. The system could both verify the availability of a ticket and perform the booking on subsequent request.

The team of engineers working on the American Airlines reservation system called their work the Semi-Automated Business Research Environment, or SABRE. Costing hundreds of millions of dollars adjusted for inflation, it went online in 1960 in a dedicated data center in Briarcliff Manor, New York, and could handle tens of thousands of phone calls a day. In 1964 it assumed all booking functions for American, and in 1976 travel agents were granted access to the system. IBM developed similar systems for other airlines, such as the PANAMAC for Pan Am and Deltamatic for Delta, before creating the general purpose Programmed Airline Reservation System (PARS), initially for use on IBM System/360 business computers. The SABRE group developed its own programming language for reservation systems, SabreTalk. By the early 1980s, reservations could be made online through the Genie and CompuServe online services, followed in the 1990s by

America Online. SABRE later went on to become Sabre Holdings, a separate company from American Airlines, which today owns the Travelocity Web site.

SABRE was one of the first real-time operating systems and the first computer system of its scale to be relied on by a major industry like the airlines. Its development pioneered the use of computer systems for business functions and was a major boon to the travel industry itself. When the airlines were deregulated in 1978 and new companies entered the industry, they needed to acquire reservation systems quickly in order to compete with the established airlines. In one case, the new company Texas Air purchased the older and poorly performing Eastern Air Lines purely to acquire Eastern's System One computerized reservation system.

An early proposal by American Airlines to institute a common reservation system for the whole airline industry, one that would keep the power in the hands of the airlines rather than the travel agents, was refused by the rest of the industry because of concerns that it would invite an antitrust investigation. The first multiaccess reservation system was instead introduced in the United Kingdom, when Travicom was introduced by Videcom International in 1976, allowing travel agents to book British flights with 49 different airlines. Videcom introduced similar systems throughout the world.

Today, every airline and regional carrier has its own reservation system. Global distribution systems (GDSs) connect the major airlines with travel agencies and travel Web sites, allowing customers to book flights from point A to point B and to compare prices and other factors across multiple airlines. The GDS tracks itineraries and creates interconnectedness between the airline reservation systems but does not itself maintain inventories (the lists of all flights and all the available seats on those flights, by service and booking class). Use of GDSs makes it easier for passengers to coordinate itineraries that include flights on multiple airlines, in which case the GDS retains information about the entire itinerary, while each airline's reservation system holds the portion of the itinerary relevant to that airline. In the 21st century, SABRE—along with one of its competitors, Amadeus—functions as both a GDS and a reservation system; each functionality behaves as a separate system.

The use of computerized reservation systems has allowed for much more sophisticated reservation

systems than were used in the past or even in the early days of computerized systems. Prices are more easily adjusted, for instance, which rewards early bookers; day-of-departure business-class upgrades and standby seat-fillers fill the flight as close to capacity as possible in order to maintain the airline's profit margin. Reservation systems also track massive amounts of data, and problematic overbooking situations can be avoided by monitoring trends in this data. Flight schedules, too, can be adjusted if trends in underbooked flights are revealed.

These new reservation systems have also come with problems, notably including the delays caused by US Airways' 2007 integration of its reservation system with that of America West, an airline with which it had merged in 2005. The integrated system was unable to communicate with ticketing kiosks, requiring all passengers to check in at the counter. This situation almost doubled the number of passengers at the counter, and lines were long enough to cause passengers to miss flights. Only one-eighth of US Airways' flights departed on time during the weekend the new system was launched. In 2010, Virgin Blue's New Skies reservations system, owned by Accenture, crashed multiple times, resulting in hundreds of canceled flights and a multimillion-dollar dispute between the two companies. A subsequent system crash in 2011 required Virgin to manually process passengers and baggage, causing departure delays more than an hour long throughout the United States.

Ticketing systems use rule sets, routing maps, and data about information that affects ticketing prices (e.g., taxes and tariffs) to construct the fare in response to requests fed into the system by an agent or other software. Class of service and booking conditions affect the fare as well, and because of airport taxes, fares vary for any available city pair. The fare basis code is the set of all fare conditions. Ticketing systems don't just determine fares; they issue and store electronic tickets and electronic records of paper tickets (which are now the minority of airplane tickets).

The growth and popularity of online comparison and reservation sites like Expedia and Orbitz has led to a push in the industry to develop new reservation and ticketing systems. The industry group International Air Transport Association (IATA)—which developed industry standards for paper tickets and baggage tags and the three-letter codes used

to designate airports—has asked the Department of Transportation for permission to move away from Edifact, the computer language used for ticketing systems for four decades, in favor of the more modern XML (extensible markup language). Part of IATA's goal is to make it easier to transition to a new ticketing and distribution system, one that can tailor options and prices to the customer, in order to let the airlines compete with comparison sites. The request was filed in 2013. One complaint about the plan is that tailoring tickets to customers will require collecting personal information from them in an age when customers are increasingly concerned with privacy.

Airline Flight Scheduling

When most people fly, they do not think too carefully about airline flight scheduling—unless such scheduling directly influences their personal plans. Even in the event that personal plans come in conflict with changes in flight schedules, passengers are only rarely cognizant of even a few of the

many factors that influence airline flight scheduling. Much of airline flight scheduling is maximized through automated procedures, which are based on mathematical models. These models are incredibly complex. This article addresses only a portion of the factors included in those models. The broad scope of factors that can influence airline flight scheduling include very large-scale elements, such as weather, and major social events, such as a presidential inauguration or widely celebrated holidays (Christmas, Thanksgiving, etc.).

Not only must purely logistical considerations come into play when determining flight schedules, but staffing issues must also be taken into consideration. To operate, each flight requires a crew, including pilots and flight attendants. In terms of basic material logistics, each plane requires a certain amount of cargo, baggage, and equipment needed for safe and comfortable operation.

The subject of airline flight scheduling is not without controversy. In fact, serious allegations have been made regarding the way schedules and alterations in those schedules are typically handled. Furthermore, critics claim that precautions could be taken to prevent conflicts from occurring in the first place.

Elements

Flight scheduling is at the core of what makes our modern air travel systems work. Scheduling, and many other functions of modern air travel, must take into account departure and arrival times. Additionally, each airline possesses only so many vehicles of each model. Thus, aircraft availability must be taken into consideration in flight scheduling models.

We live in a capitalist society, and the air travel industry is likewise oriented toward capitalist goals. Within the realm of capitalist-oriented transit systems, the ultimate goal of maximizing profits is met by matching seat capacity to passenger demand. By keeping seats at maximum possible capacity at all times, airlines seek to reduce costs. For this reason, airlines focus on fuel consumption and maintenance per passenger in the name of maximizing profits. In this way, when flight scheduling takes into consideration distance between destinations, desirable flight times, operating restrictions, aircraft operating costs, and staffing considerations, airlines are able to achieve

Passengers at Charles de Gaulle Airport in Paris, France, consult a flight information display showing dozens of cancelled flights caused by the eruption of Iceland's Eyjafjöll volcano in April 2010.

their profit goals while getting passengers where they need to go.

Staffing considerations are a complex and multifactorial element of flight scheduling. The crew of each vehicle requires a number of critical personnel. These on-board personnel include pilots and flight attendants. These personnel are regulated by various interests, including corporations, federal agencies, and labor unions.

A standard flight requires two or three fully qualified pilots to fill the positions of captain, first officer, and flight engineer. The captain is the individual who actually flies the plane and is ultimately responsible for the craft. Additionally, she makes all major command decisions. She also manages emergencies with both the aircraft and the passengers. The first officer serves as the second in command of the craft. He has access to controls identical to those of the captain. Furthermore, he has the same level of training as the captain. The primary role of the first officer is that of safety; he provides second

opinions on piloting decisions and seeks to prevent pilot error. Depending on the model of the aircraft, the plane may or may not have a flight engineer. Flight engineers are fully trained pilots. Under typical nonemergency circumstances, flight engineers do not fly. Their role is to monitor the plane's instruments; in newer planes, such monitoring is performed by computerized systems. It is likely that the role of flight engineer will be phased out entirely in the near future.

Second only to the cockpit crew, flight attendants are critical to the smooth operation of the aircraft. The standard practice is to have one flight attendant per 50 passengers. By this metric, a 200-passenger plane will have four flight attendants. Flight attendants tend to the needs and comfort of the passengers and keep other aspects of the flight running smoothly. Other crew critical to maintaining flight schedules are the runway crews. These individuals prep planes before takeoff and tend to the plane's needs after landing. Their duties include, but are not limited to, refueling the plane, aiding the pilots in parking the plane, and loading baggage and other cargo on and off the craft.

There are other issues that may be taken into consideration in airline flight scheduling. Logistic concerns regarding the movement of various components must also be incorporated into plans. These include the flow of passengers from concurrent flights, concurrent cargo flows, and the movement of aircraft and flight crews through time and space. Mechanical issues, such as aircraft equipment issues and maintenance, must also be taken into consideration. Finally, issues directly relating to passengers, such as ticketing, check-in, baggage drop-off, and security concerns may also serve as important components of flight scheduling models.

The Cause of Delays

The Federal Aviation Administration (FAA) considers a flight to be delayed when it is 15 minutes later than its scheduled time. By similar FAA regulation, cancellation is said to occur when the airline does not operate the flight at all. Either delay or cancellation may occur for any number of reasons. These may include maintenance problems, staffing shortages, staff strikes, aircraft cleaning, standard maintenance, baggage loading and unloading, fueling, extreme weather (which may vary based on regional

conditions), air traffic congestion, late arrival of aircraft scheduled for subsequent flights (such an event may have a cascading effect), security issues, and glitches on behalf of the airline.

Delays in flight schedules are not universal in their cause, and their cause may vary from airport to airport. In fact, some airports consistently experience issues that are unique to that facility. Some of these issues are based on natural geography, others are based on placement of population bases or human activity centers. Due to its proximity to the San Francisco Bay, the San Francisco International Airport frequently faces delays due to fog. Similarly, Burbank's Bob Hope Airport often faces delays and other difficulties due to high winds caused by proximity to the Verdugo Mountains.

Philadelphia International Airport does not face unique issues due to its terrain but rather to its social location. The occurrence of a delay spreading from one airport to another due to late arrivals is not uncommon. However, due to its location between New York City and Washington, D.C., the Philadelphia airport frequently must cope with the fallout of cascading delays from those ports of call to a greater degree than occurs at other airports.

Controversy

There is no debating that air traffic delays are very inconvenient for passengers and crews. Additionally, they have a negative impact on the profitability and public relations efforts of airlines. The controversial element of air flight scheduling relates to the cause of delays. Some critics have argued that airlines overbook flights recklessly in the name of profit; this, in turn, causes delays. Others claim that airline errors in flight scheduling and other glitches are the cause of delays. According to a 2007 *USA Today* analysis, airline glitches are the number one cause for flight delays. This accusation challenges the common perception and claim by the airline industry that weather or heavy air traffic days (such as Thanksgiving or Christmas) are the primary cause for delays.

Such glitches may include ground crews taking too long to refuel, preventable mechanical breakdowns, and pilot shortages. Staffing shortages have been a particularly difficult problem in the modern era that has been perpetuated by high turnover. Airlines do not deny that the current system must be improved. However, they still blame weather

conditions for the vast majority of delays. If the accusations of preventable glitches reflect reality, then the delays that cause so much frustration and lost revenue to both passengers and airlines could, in fact, be solely the fault of airlines. This would be reason for significant reform.

Airline Industry

Aviation was born at the dawn of the 20th century as a result of the dedication and passion of many people, especially entrepreneurs, throughout several centuries. Up to the 1900s, most of the flying initiatives and experiments were carried out by visionaries, enthusiasts, scientists, and even military figures. One of the first recorded flights

occurred on the afternoon of September 19, 1783, in Paris, France. A hot air balloon flew for around eight minutes for a total distance of about 2.5 miles carrying onboard a sheep, a cock, and a duck. The animals survived the journey, demonstrating the existence of breathable air above the surface. Later that year, on November 21, two people—Pilâtre de Rozier and the Marquis d'Arlandes—flew over Paris for about 5 miles (8 kilometers).

In the 1800s, many other ballooning initiatives took place, mainly for leisure or entertainment purposes, although some included distribution of letters (the beginning of air postal service), all using balloons. On November 7, 1836, Charles Green and two passengers took off from Vauxhall, London, and landed in Weilburg, Germany, a total flight distance of 49.7 miles (800 kilometers) and flight time of 18 hours; on October 19 to 20, 1887, Louis Godard took off from Leipzig, Germany, and landed in Tarnow, Poland, a total flight distance of 1,181 miles (1,900 kilometers) and flight time of 24 hours.

The invention of aircraft is often credited to Sir George Cayley (1773–1857). In 1799, he advanced the concept of a heavier-than-air machine that could fly. The machine had many of the components of the modern airplane, including fixed wings and separate systems for lift, propulsion, and control.

Not without a certain degree of controversy, the first flight is credited to the Wright brothers—Orville and Wilbur—on December 17, 1903, in Kitty Hawk, North Carolina (United States). The aircraft, with capacity for one person, was airborne for only 12 seconds and flew for about 273 yards (250 meters). Despite the humble beginning, it marked the start of an outstanding adventure that would lead man to dominate the skies in the coming decades.

Prior to World War I, aviation remained in the early stages with few initiatives taking place, concentrated mainly in the United States and Europe. It is worth mentioning that the first freight commercial flight took place on November 7, 1910, between Dayton and Columbus, Ohio, and the first regular passenger air service started some years later on January 1, 1914, between Tampa and St. Petersburg, Florida, and ended on March 31 of that year. By that time, the sector was struggling with major limitations in the knowledge and development of aeronautical technology. As a result, aviation services

An Eastern Air Lines plane, promoted as part of the "The Great Silver Fleet," arrives at the Washington, D.C., municipal airport in July 1941. Eastern Air Lines operated from 1926 through deregulation in the late 1970s, finally succumbing to high costs, competition, and a significant debt load. The airline ceased operations in 1991.

were carried out with considerable limitations: aircraft had very low capacity both in terms of payload and volume, and most flights were only possible during daylight and in good weather conditions.

Throughout this period most efforts were in the transport of mail. In the first decade, however, as Camille Allaz eloquently writes in his history of air-cargo and airmail,

. . . at best, [letters] were placed on board an aircraft, which carried out a brief flight over the airfield before landing at its point of departure: one cannot therefore really describe these as *postal transport*.

During the second decade, aeronautical technology evolved enough to enable the construction of capable aircraft, and air mail route initiatives multiplied worldwide to include the United States, Great Britain, Italy, South Africa, Italy, Germany, Egypt, Sweden, and Denmark.

World War I marked a watershed in aviation history. Governments finally grasped the full potential and versatility of aircraft, which could be deployed on scouting missions, attacks, or

transport, and they massively invested throughout the war period in the development and construction of aeronautical technology. For example, in France, where there were about 600 aircraft in 1914, around 34,000 aircraft were built during the war. A similar leap would occur some decades later, during World War II, when civilian aviation activity was brought to a sudden halt and aeronautics research and development for military purposes would receive major incentives.

Between the World Wars: 1920s to 1940s

Near the end of World War I, on August 28, 1919, six aviation companies from six European countries got together to found the International Air Traffic Association, which would later become the International Air Transport Association (IATA). This organization was meant to promote and coordinate the development of international air traffic and to defend the interests of its member companies.

During the war, aviation technology underwent significant developments. Afterward, those developments spilled into the civil arena, feeding the start of numerous aviation companies for passengers, freight, and mail in many countries

worldwide, including Australia, China, Colombia, Japan, and the United States, as well as European nations. A major breakthrough for aviation was made in the United Kingdom in the 1930s with the invention of radar.

This technology could be used either on the ground for detecting solid objects (aircraft) in the air, or on board aircraft for guidance. Radar is still the backbone of today's air traffic control. Other significant improvements, but related to the air cargo business, also took place in the 1930s with the development of the first aircraft that could carry freight in the lower deck (belly). Aircraft could now simultaneously transport passengers and goods, enabling aviation companies to offer both services in the same operation.

In Europe, in the initial phase, freight was the main driver of aviation's development seen because a significant part of the continent had communication and transport networks destroyed by the war and there was urgent need for securing the conveyance of mail, bedding, medicines, and food to the affected regions. Soon after, both passenger and mail segments would grow and have an equal share of responsibility in building the sector. Interestingly, in Europe the passenger segment has always been vital, with most aviation companies having mixed transport services (for carrying people, mail, and freight) and very few entirely dedicated to the transport of either mail or freight.

This situation was in contrast with the United States, where the growth of aviation was mainly driven by the mail transport services. The U.S. Post Office Department (US POD) was closely connected with the history of civil aviation for the first decades and, due to the relatively modest level of passenger and general-freight services, became the main aviation services' customer. The US POD found in this mode of transport a very suitable substitute to the traditional ones—sea and train—owing to its superior speed, a factor of paramount relevance for postal services, and in 1927, it established the first transcontinental air route linking San Francisco and New York.

However, the importance of the mail services would be brief as, throughout the remaining period between the world wars, the general-freight segment grew at a faster pace than the mail segment and would eventually outpace it. The segment that had driven aviation's evolution for the

first decades has been definitively relegated to an inferior position.

Growth Period: Mid-1940s to 1970s

Following the halt brought by World War II, civil aviation dived into a period of tight economic regulation. In 1944, the Chicago Convention (formally called the Convention Concerning International Aviation) was held with the purpose of defining an international regulatory framework for the future development of international civil aviation. However, the rift between participating countries was so deep that no overall agreement was achieved. On the one side, some countries, like the United States, sought a more liberal and open approach, on the other side, others—mostly European countries with their economies near ruin and with extensive wartime damage—preferred a close agreement where all economic and commercial matters would be under the supervision of one organization.

Even so, two main achievements were attained: first, several freedoms of the skies were mutually recognized, except in special circumstances such as war. These rights would later form the bases for future international bilateral agreements. Second, the International Civil Aviation Organization (ICAO) was established, under the auspices of the United Nations, with the clear mandate of developing the principles and techniques of international aviation and fostering the planning of international aviation.

In parallel, aviation companies recognized the need for an organization for discussion of aeronautical technical and operational issues that could defend their interests. The former International Air Traffic Association was relaunched and renamed under the designation: International Air Transport Association (IATA). ICAO and IATA are the two main bodies in civil aviation. They set most of the international standards, rules, and norms, as well as coordinate diverse business issues, such as rates and tariffs, schedules, or access to airports.

In the absence of a universal international law and in order to initiate international air services, each country was forced to engage in direct negotiations with every other country it wanted to fly into. These bilateral negotiations resulted, naturally, in a vast quantity of bilateral agreements. These agreements were normally conducted under

the auspices of IATA. The first bilateral agreement signed in 1946 was designated the Bermuda Agreement between the United Kingdom and the United States. The Bermuda Agreement served thereafter as a role model for other negotiations. The bilateral agreements impose rigid norms over several market issues (see Table 1).

In practical terms, bilateral agreements prevented competition among airlines, as capacity and fares were agreed and revenues were shared. After some years, a large number of bilateral agreements had been signed, ruling the international aviation sector. At the national level, the picture was not so different, with countries adopting either a public or a private, but heavily regulated, aviation sector. In any case, the aviation market was heavily regulated: fares, access, schedules, and routes were not defined by aviation companies but by public authorities. The outcome was an artificial market free of competition. Interestingly, these constraints did not hamper civil aviation's growth but the very opposite—the sector developed at a fast pace.

Throughout the 1940s, the civil aviation market gradually shifted its business focus toward the passenger segment. Several factors contributed to this change. First, the passenger segment became dominant in terms of revenues. Second, governments' attention turned toward this segment. Their

primary concern was assuring adequate aviation services to populations in order to promote the desired national equity and cohesion. Additionally, the growth of the passenger segment gave civil aviation a political role, as people complained and demanded further rights, whereas freight business has remained essentially within private scope that, naturally, does not complain. Finally, freight transport was in most cases already conveniently secured by surface communications, mainly rail transportation. Despite the growth of aviation, the volume of goods airborne was still modest.

In the 1950s, a second major technological breakthrough occurred in the aviation sector: the introduction of jet engines. These engines provided superior performance, in terms of both thrust and speed, compared to the former propeller engines, making possible the design of larger and faster aircraft. Larger aircraft meant more capacity (in terms of volume and weight) and faster aircraft meant longer routes and fewer stopovers.

The decades after World War II were very favorable for air cargo business, with rising demand for freight services sparked by robust economic development of the world's principal economic blocks, and cheap oil prices. Many companies that carried freight exclusively entered the field and became responsible for most of the market. This was particularly notable in the United States, and the success was such that in 1949 these operators carried 83 percent of the freight traffic and accounted for 73 percent of the revenues of the air cargo market.

Many passenger aviation companies (for example, American Airlines) also provided freight services. Freight was commonly carried on the lower deck of passenger aircraft, as technological development was rendering larger aircraft with enough space for passengers' baggage, mail, and other freight. Notwithstanding the growth of the freight sector, provision of freight transport services remained largely a side (or secondary) business meant for earning some extra revenues by filling available space.

The lesser relevance of freight business led companies to minimize the business's resources. In many of them, freight business consisted of selling, commonly through block space agreements (usually at a negotiated cost lower than the spot market but providing the carrier a fixed income), the available space on the aircraft's lower deck and, eventually, a

Table 1 Bilateral agreements

Issue	Common Features
Designation	Single designation
Routes	Point-to-point routes governmentally defined
Capacity	50 percent for each country
Fares	Decided at IATA tariff conferences
Ownership	Publicly owned Privately owned by national companies
Revenues	Obligatory 50:50 percent revenue pooling

portion of the upper deck to third-party agents—freight forwarders—responsible for marketing, negotiating, and operating freight business. Consequently, over time, passenger companies would lose to freight forwarders most, if not all, contact with freight customers.

The dedicated freight companies' domain, however, faded out and by 1960 passenger companies controlled over 80 percent of international traffic and around 70 percent of the scheduled world freight traffic (with similar figures in the United States). Two main reasons may be pointed out: first was the lack of suitable aircraft for freight operations, as they were primarily tailored for passenger operations. Available aircraft lacked a reinforced fuselage and floor, ample doors, or internal arrangements for anchoring freight, which hindered freight-related operations.

Second, a more favorable business model for passenger airlines existed. Recall that passenger companies run two businesses in parallel: passenger and freight, and therefore they may allocate the flight's costs in their best interest. For example, passenger companies' freight rates can be lowered to cover only the increase in fuel consumption (marginal cost), while allocating all the other costs (such as aircraft acquisition and maintenance, crew or taxes) to passenger operations. On the other hand, freight companies run a single business, that is, freight operations. They have to allocate all the costs to this business. Inevitably, this results in higher freight rates.

It is worth mentioning that during this period a new breed of highly competitive companies—integrators—entered the market offering an innovative service: express freight services. Yet, it was not until the 1980s that they gained momentum.

Liberalization Period: Late 1970s to the Late 1990s

For more than 30 years, the civil aviation industry evolved within this environment. The outcome was a stagnant market, with many companies depending on subsidies in order to survive. The absence of competition, the inflexibility of rules, and the lack of stimulus led companies to reach a dead end, with enormous deficits and low efficiency. Other problems of regulation included restrictions on trade, distortion of the overall pattern of services, lack of incentives to modernization or improve, and no focus on the traveler. Carriers repeatedly reported

low load factors, and many were undercapitalized, inefficient, and unprofitable. As a consequence, fares were too high, as were labor costs. The oil crisis in the early 1970s further worsened the carriers' problems.

By that time in the United States, the civil aviation industry had reached an unsustainable situation, with government obliged to inject huge amounts of governmental subsidies in order to keep carriers operating. Furthermore, some voices, supported by several studies and reports that stated the problems and weaknesses of regulation, rose against the regulatory framework. There was an expectation that airline markets could be quite competitive and that even those with little competition should keep costs and prices down. The Civil Aeronautics Board conducted some research and found no advantages in regulation; consequently, it advocated deregulation. This situation evolved until October 24, 1978, when President Jimmy Carter signed the Airline Deregulation Act, which fully deregulated the U.S. domestic market.

After deregulation, the market underwent some distressing times, with many volatile entrants and with incumbents facing adaptation problems. Increased competition, a "boom" in air travel, and reduction of fares were other short-term effects of deregulation. New entrepreneurial carriers entered the scene, offering innovative products, such as frequent flyer programs and promotional fares. Incumbents followed their lead and also adopted a commercial-driven business attitude, becoming more competitive. However, after years of entries and exits, most of the new entries as well as some long-time carriers went into bankruptcy and an oligopolistic market again developed, with a diminution of real competition.

The star-shaped network, called as hub-and-spoke, became the common configuration for scheduled airlines, which reduced the number of direct flights. Furthermore, many routes disappeared because they were not profitable, which reduced the number of places served.

In terms of quality of service, an overall reduction of the quality of food, leg room, and in-flight service occurred. Moreover, overbooking and bumping of passengers became relatively frequent.

Despite the disturbing times and problems, in general terms, deregulation has been advantageous. After a decade of deregulation, fares fell by

about 7 percent on major routes, passenger boarding rose by 55 percent, scheduled-revenue passenger miles grew by over 60 percent, and employment increased by 32 percent. In 1977, 37 percent of passengers traveled using discounts; this increased to 91 percent in 1987.

After opening its internal market, the United States also engaged in relaxing the international one. Thus, in 1978, various liberal bilateral agreements were signed with European countries, namely, the Netherlands, Germany, and Belgium, and in the following two years with various Asian countries, including Thailand, Singapore, and Korea. Other countries have followed the United States example and deregulated their domestic markets. Canada, Australia, and New Zealand are some examples of countries that had already relaxed their national and international markets.

The pace toward liberalization of these markets was slower and less systematic than in domestic aviation, mainly due to opposition from some countries that refused to open their markets to competition. They feared that their companies would not withstand a competitive market and would lose some of the economic benefits of a regulated environment. Generally, the first move to liberalization has been relaxing the existing bilateral agreements through increased capacity limits, permitting more airlines onto routes, and increasing competition between airlines.

An interesting example exists in Australia where the government has granted the right (the sixth freedom of the skies) to some Asian companies (third-country carriers) to carry passengers from Australia to Europe via their hub, in order to increase competition and reduce tariffs. However, the move toward a global market has been painful and slow, the encouraging results and the increasing pressure from stakeholders have been pushing governments and regulatory boards to open their aviation markets.

The evolution of the European Union aviation industry was mirrored elsewhere, with countries regulating their own domestic aviation and creating bilateral agreements with other countries. These bilateral agreements that governed international aviation have evolved from the 1944 Chicago Convention. This framework developed until 1957, when the Rome Treaty was signed. The Rome Treaty represents the beginning of the European

community instituting the rules for a common market, and the Economic and Monetary Union. Moreover, the treaty envisaged free mobility for people, goods, services, and capital within the community, calling for the elimination of all protective barriers and obstacles. Under the treaty's philosophy, the existing system of aviation regulation was unsustainable, as the current system of airline regulation was anticompetitive and in opposition to the competitive spirit of the treaty; furthermore, market access or price-fixing restrictions worked against the freedom to supply services.

The European Commission was charged with the implementation of the Rome Treaty. However, at the outset, the mission was quite complicated as forces favored the existing regulatory system. Three main reasons can be pointed out. First, transports had a different position, under the treaty, than the other services. Title V (articles 71 and 80) relinquishes to the Council of the European Union the decision to rule and to legislate the Common Transport Policy. Second, air and maritime transport were not initially included in the Common Transport Policy (no. 1 of article 80). Third, countries and industry also favored the existing system and the status quo. These features reduced the European Commission's authority and, despite all initiatives, the market remained heavily regulated for several years. Changes arrived slowly and in different ways.

In the face of a continuous absence of more open European policies, some countries reformed their own domestic markets. The United Kingdom was the most active one and from 1984 until 1987 relaxed its bilateral agreements. Table 2 presents various liberal bilateral agreements features.

The first responses to liberalization were rather positive, with newcomers entering and incumbents responding accordingly. Furthermore, the European Commission and scholars presented several reports and studies that emphasized the inefficiencies of the European air market and benefits of a more competitive market. The small unit costs of the developed European charter industry and the United States' deregulation were also used as evidence of the potential benefits of liberalization.

The European Court of Justice also took an important role in changing European transport policy in 1974, with the *French Merchant Seamen* case declaring that rules governing competition in the

Rome Treaty applied to aviation, and in 1986, with the *Nouvelles Frontières* declaring that national rules should be in conformity with European laws. Its deliberations against the European Council and the existing regulatory system strengthened the voice of the European Commission. Finally, the European Council decided to introduce liberalization slowly and by phases. The underlying philosophy was to introduce evolution rather than revolution within the aviation market, as had happened within the U.S. domestic market in 1978. The Council determined that liberalization would take place in three steps. In each step, a set or “package” of legislative rules would be defined, aimed at the establishment of a free and competitive market akin to that within the United States.

The First Phase began in 1988, bringing timid winds of change, the Second Phase began in 1990, strengthening and spreading the competitive spirit; finally, the Third Phase began in 1993, establishing a competitive environment in the European market but only after a transition period until 1997. The European liberalization was one of a kind. Never in human history has such a large number of countries opened their domestic and international market to competition. Unlike the United States’ deregulation process, the European

Union’s aviation market did not undergo significant turmoil. Two main reasons may be pointed out: first, the process was incremental rather than sudden, leaving enough room for market agents to adapt, and second, the liberalization only affected the internal market of the European Union, but a significant part of the business came from non-European business that remained unchanged. The most notable consequence of the liberalization process was the rise of low-cost companies in the European Union.

The Twenty-First Century

The transition to the new millennium proved rather harsh for the aviation sector, as new dangers emerged in the landscape: economic turmoil, ever-increasing competitive forces from within and outside the aviation business, rocketing fuel prices coupled with an increasing awareness of sustainability, and quantum technological developments. Such forces began shaping the aviation business and leading many agents to find new ways of doing business.

The first decade of the 21st century will be recalled by the appearance of new forms of threats in aviation, namely, terrorism and diseases. The aviation sector has been for a long time a preferred

Table 2 Liberal bilateral agreements

Countries (Date)	Features
United Kingdom–Netherlands (1984)	Liberal route access and capacity with consultations Country of origin fares rules
United Kingdom–Luxemburg (1985)	Liberal route access and capacity Double disapproval on fares
United Kingdom–France (1985)	55:45 on capacity Liberal access No changes on fares
United Kingdom–Belgium (1985)	Liberal route access and capacity Double disapproval on fares
United Kingdom–Switzerland (1985)	Liberal route access and capacity Country of origin rules only for discount fares Minimum conditions for special fares
France–Federal Republic of Germany (1986)	Only greater freedom for route access

Source: Reis, Vasco. “The Performance of the European Liberalisation Process—An Evaluation of the Scheduled Air Transportation Market.” Master of Science Thesis, Oporto University, Portugal, 2005.

tool for terrorism acts. Common tactics have included bomb attacks or hijacking of aircraft. Yet, nothing was so devastating as the terrorist attacks of September 11, 2001, in the United States. The world woke up differently in the aftermath, and immediately governments all around the world imposed strict security and safety measures in the aviation production chain, particularly airports and air transport companies. Examples of safety and security measures include reinforcement of aircraft cockpits, universal baggage and freight screening, and thorough passenger screening procedures. The measures appear to be effective, since no other similar event has occurred. Nevertheless, the danger remains, as evidenced by the discovery in 2010 of small explosive devices in two cargo aircraft heading to the United States. In parallel, another very different but still dangerous threat emerged on the horizon, that of a new breed of contagious diseases, such as the severe acute respiratory syndrome (SARS) epidemic in Asia in 2002 and 2003, and influenza virus in Mexico in 2009. Aviation was unfortunately a victim of its own success. A threat that some decades ago would be easily contained within a specific region can now spread worldwide at unprecedented speed using the air transport networks.

Economic Turmoil

The world economy exhibits a cyclic nature, with periods of around 10 years. There were important economic downturns in 2001 and again in 2008, which is yet to be recovered from five years later. The state of the economy has a significant impact on the aviation sector. In periods of economic downturn, people fly less and less freight is shipped. Recent studies found that the air cargo business tends to grow between 1.5 to 2 percent above global gross domestic product (GDP), while others concluded that a correlation exists between airlines' net operating margin and the world's GDP. The aviation business was still recovering from the 2001 world economic recession when it was hit hard in 2008 with the subprime crisis in the United States and the subsequent economic crisis in the European Union and elsewhere. Caught in the middle of the economic turmoil, aviation agents could do little except survive and look for secure refuges. This has appeared in the form of either vertical, that is, between agents operating in different businesses

(for example, airlines and airports), or horizontal, that is, between agents operating in the same business (for example, airlines), agreements. Agreements bring synergies, generate opportunities for cutting costs, and ultimately lead to reduction in competition (that is, market concentration).

Agreements and Alliances

Agreements can include a wide set of forms and include multiple functions. The simplest types of agreements include only matters of a commercial nature and technical and operational aspects of the business. They entail low commitment and are often established on an ad hoc basis when necessary. At the other extreme, the most complex types of agreements entail long-run commitment and involve any sort of exchange of assets (including, but not limited to, terminal facilities, maintenance bases, aircraft, staff, traffic rights) or capital. Among these, the most developed refer to mergers and acquisitions between companies. However, governments seldom allow their national companies to merge or be acquired by foreign ones, for matters of sovereignty and economic protection.

As such, these types of agreements are usually limited to companies registered in the same country. In the United States, multiple mergers and acquisitions have recently occurred, for example, Continental Airlines merged with United Airlines in 2010, Delta Air Lines merged with Northwest Airlines in 2008, and American Airlines merged with US Airways in 2013. The most notable exceptions are in the European Union, owing to the European liberalization process and the implementation of the internal market. Multiple movements have also occurred. As an example, Lufthansa Airlines acquired a set of other airlines, including Brussels Airlines, Alitalia, Swiss International Air Lines, AG, and Austrian Airlines. Also, Air France merged with KLM, and British Airways merged with Iberia.

Airlines responded to the governmental restrictions on mergers and acquisitions through the establishment of alliances. The members of an alliance establish a set of commercial agreements among themselves, aiming to achieve the highest possible level of synergies within the freedom granted by the national governments. The benefits for the customers include a seamless travel experience in terms of level of service, tariffs, timetable, rights, or privileges.

There are currently three global alliances: Star Alliance, SkyTeam, and Oneworld. Available statistics for 2012 show that three of every four passengers were carried on one of these three global alliances. Each alliance includes a major airline from the United States (United Airlines in Star Alliance, Delta Air Lines in SkyTeam, and American Airlines in Oneworld), Europe (Lufthansa in Star Alliance, Air France in SkyTeam, and British Airways in Oneworld), and Asia (Singapore Airlines in Star Alliance, Korean Air in SkyTeam, and Cathay Pacific in Oneworld), in addition to multiple regional members. In 2012, Star Alliance was the largest global alliance with a total of 28 members and traffic of 650 million passengers.

Low-Cost Airlines

The low-cost airline (LCA) concept is arguably the most notable consequence of the deregulation and liberalization wave sweeping the air transport sector worldwide since the late 1970s. Over a period of three decades, the low-cost segment continued to grow, bringing significant changes to the air transport sector's status quo and impacting societies and economies (for example, through tourism and regional development or enhancement of populations' accessibility). Low-cost airlines, low-fare airlines, no-frills airlines, discount airlines, and budget airlines are just some of the terms commonly used to designate the new breed of air transport companies that emerged in the late 1970s in the United States after the air transport market's deregulation, in Europe in the late 1990s, and since then worldwide.

An LCA is an airline that offers very low fares and airport-to-airport services. In order to make a profit, LCAs follow very specific business models perfected to minimize costs and improve revenues. Differentiating features include direct sales of tickets, absence of frequent flyer programs, utilization of cheaper secondary airports, higher daily utilization of aircraft, paid in-flight services, paid checked luggage, and a higher density of seats.

Despite offering only direct connections and no amenities, the concept has proved very successful everywhere. Available statistics by OAG (formerly known as the Official Airline Guide) reported in 2012 a market share for LCAs of around 26 percent in terms of total seat capacity, which is a notable amount bearing in mind that

many countries remain regulated. In mature low-cost markets such as the European Union or the United States, the market share is stable at around 30 percent and 20 percent, respectively (in terms of total seat capacity). Despite the collective success of the LCAs' business model, available statistics show that airlines' actual rate of survivability is relatively low, with the majority going out of the market within five years of operations. What happens is a constant flow of new entries that is greater than the flow of companies that go out of the market. Indeed, sustainable profitability of an LCA business model is particularly difficult to achieve. Good examples are Southwest Airlines in the United States and Ryanair and Easyjet in Europe.

Other Modes of Transport

Competition comes not only from within the aviation sector. Increasingly, other modes of transport have been gaining a competitive edge. In the passenger market, the most notable competitor is the high-speed train (HST) or high-speed rail (HSR). Studies demonstrate that up to distances of around 310 miles (500 kilometers), HSTs can be as much, if not more, competitive than air transport. The main competitive advantages are the following:

- HSR stations are typically located in city centers, while most airports are in the outskirts, leading to longer access times.
- HSR have less stringent safety procedures, leading to faster and more comfortable security screening procedures.
- HSR services tend to have higher frequencies, which lead to better quality of services and shorter waiting times.
- HSR prices are often in line with airfares.

Beyond 310 miles, the higher speed of aircraft prevails over the other factors.

A similar trend is also visible in the freight market. Recent years have seen a progressive incursion of road and sea modes into markets traditionally captive of air transport. Although being by far the fastest mode of transport and highly reliable, air transport is also the most expensive. A rule of thumb is that an air consignment is 10 times more expensive than a sea consignment. Such difference is enough to make customers carefully reflect on the importance of time

for their goods, particularly in times of economic recession. In parallel, sea, road, and rail transport agents have been increasing their levels of reliability and, supported by technological developments, reducing transit times. The same trends have not been matched by air transport companies, resulting in a progressive shrinkage (and eventual overcoming) of the competitive position of air cargo services. Also, consumer markers have been changing. The rate of creation of high-value and new mass market products is decreasing, and those existent are maturing toward commodities. As these industries mature, shipping time has become a less critical factor.

Fuel Prices and Sustainability

Airlines' fuel costs represent around 25 percent of an airline's cost structure (market average values). Therefore, variations in fuel prices have an important impact on airlines' profitability. Fuel price is related to oil prices, and oil is very much a commodity. The price freely fluctuates on the market in relation to its availability and as influenced by speculation. Although airlines can protect themselves against sudden market fluctuations by hedging future fuel purchases, nothing can be done against a sustained upward trend in fuel prices.

As recently as 2008, oil prices rocketed to unprecedented values, rising above the threshold of US\$140 per barrel (compared with US\$60 in mid-2007). This evolution hit the aviation sector so hard that most companies decided to introduce fuel surcharges. By mid-2008, oil prices start reducing again until reaching normal prices by the end of that year. Instability in oil prices started in the 1970s and there are no reasons for slowing down as the finite sources of oil are being exhausted at a fast pace. Airlines are under increasing pressure to reduce fuel consumption and to find suitable alternative fuel sources.

Aviation is an intensive energy-consumption industry. Around 100 percent of energy is derived from oil, a fossil fuel. European Union data on emissions show that the aviation sector accounts for 3 percent of total European Union greenhouse emissions (2010) and forecasts made available by the European Commission predict that, at current trends, aviation emissions are likely to double from present levels in 10 years. The aviation sector's carbon footprint cannot be neglected and agents are responding accordingly. A recent

survey found out that most airlines are aware of their carbon footprint, make that information available, and some define targets for reduction of greenhouse gases.

As an example, Air France reduced fuel consumption and carbon dioxide emissions by 12 percent between 2000 and 2006, and the U.S. airlines collectively reduced carbon dioxide emissions by 3.7 percent from 2000 to 2006. Initiatives for reducing the carbon footprint include acquisition of state-of-the-art aircraft, adoption of more fuel-efficient climb and landing approaches, and reduction of aircraft taxiing and waiting times. A recent statement by the airlines' representative association, the International Air Transport Association, referred to the strategic goal of achieving a neutral carbon footprint by 2050. Such an objective will require the development of new technology, because current jet engines are not emission free. Meanwhile, a growing number of airlines are implementing carbon offsetting mechanisms. The purpose is to compensate for the emissions by either promoting reductions in other sectors or supporting reforestation projects.

Looking to the air transport value chain, airlines are arguably the agents with minor influence in the aviation sector's carbon footprint. As they are technology users and not technology developers, they can only use what is available in the market. They have to navigate across suboptimal airspaces, designed by other agents. A growing number of airports are congested, leading to delays and other fuel-inefficient operations (studies demonstrate that aircraft in holding patterns waiting authorization to land have an increase of around 30 percent in fuel consumption, compared to consumption at cruise speed).

Technological Developments

Aviation is the consequence of technological development. Over time, the sector has been a testing ground for innovative solutions and constantly incorporating innovative solutions. Throughout its short period of life, the sector has undergone numerous technological leaps, for example, radar in the 1930s, jet engines in the 1950s, wide-body aircraft in the 1970s, and computer reservation programs for selling passenger tickets in the 1980s.

Recent decades have been characterized by major achievements in every scientific domain, which

have been transferred to the civil aviation industry, for example, composite materials for construction of lighter aircraft, biofuels for reducing dependency on fossil-based fuels, and satellite-based air traffic control. The B787 aircraft by Boeing is mostly made of composite materials, leading to substantial gains in fuel efficiency and comfort. Also, the Airbus flagship aircraft, the A380, can carry up to 900 passengers.

Another fundamental technological evolution is the Internet. The Internet rapidly became the preferred communication and distribution channel for advertising and selling tickets, enabling the development of new marketing and business strategies. The success of the LCAs is largely supported by the Internet and the possibility of selling tickets directly to passengers without the need of a travel agent.

Airline Marketing

Airlines are companies that transport people and cargo to different locations around the world. They do so using a variety of aircraft, which are large and expensive pieces of equipment requiring very high levels of safety and maintenance. Hence, ownership of a fleet of aircraft represents an important barrier to entry for would-be competitors, and there are comparatively few rivals in any particular sector. This was particularly true in the early years of the industry, when many markets were restricted to national or regional carriers, many of whom received state subsidies in one form or another.

The industry began to be transformed in 1976 when the U.S. government commenced a program of deregulation and the move toward "open skies" or "blue skies" agreements, which opened markets to a much greater degree than before. In the years since, new agreements have revealed the lack of competitiveness of some airlines and high-profile bankruptcies (for example, American Airlines, Delta Air Lines, and Northwest Airlines) and the struggles of some national carriers in Europe and elsewhere. New entrants have emerged, of course, and among these, low-cost or budget carriers have become prominent. Following the model of Southwest Airlines, budget carriers have stripped down the components of services customarily expected as part of a flight experience in order to reduce costs and airfares.

Since flying has become a mass market as tourism has blossomed around the world, new customers who would not previously have been able to afford air travel are entering the market, and their expectations of service are not always as high. These are among the factors most influential in shaping the marketing strategies of airlines.

Branding and Loyalty

In order to make airline routing more efficient and to extend the network of individual companies, many routes now share codes. In other words, two or more airlines share a particular route or flight, which is marketed in the names of all partners. This can be problematic in that passengers may be unwilling to disentangle which part of the service is the responsibility of which agency in the event of any problems. One bad customer experience—on the basis that bad news always travels much quicker and farther than good news—can damage the reputation of a number of companies that have only limited ability to control what has occurred. However, this is part of a larger problem affecting airlines, which is their lack of control over so many of the important service encounters that do so much to influence customer satisfaction overall. For example, baggage handling, excessive and intrusive safety screening techniques introduced in the wake of actual and attempted terrorist attacks, and the quality of catering in the airport might all be conflated in the mind of the customer with the responsibilities of the airline from which tickets have been purchased.

It is a somewhat contradictory phenomenon in marketing that the more effort that is expended in promoting the branding of a service, the greater the risk of loss of brand value from third-party activities. Airlines are generally not in the position of being able to conduct vertical integration to take over groundside services; indeed, the opposite approach is much more common as different components are spun off to third parties contracting through market transactions.

Despite these issues, airlines have used brand loyalty as a primary means of connecting with customers. Air miles schemes offer reduced-cost or free tickets to frequent travelers. These are particularly valuable to large-scale corporate customers who have regular schedules to fulfill and who might also value the partnerships with car rental or accommodation providers that are often included

within packages. Internationally, there is a trend for loyalty card schemes of this sort to broaden their coverage to more partners and deepen their coverage to more goods and services.

One mode of attracting customer attention in the past was the use of young women as stewardesses on airplanes. More or less blatantly, airlines hired only attractive and young women with a minimum height regulation (based on safety regulations) and promoted their lines through the bodies of the stewardesses and their compliance to customer wishes. The job still appears a glamorous one in many parts of the world. However, greater awareness of gender and workplace relations in airlines in the developed world has required more diversity in this occupation, and the nature of advertising has also moved from explicit sex appeal to such factors as comfort, luxury, and reliability.

Segmentation

One of the most important marketing techniques for airlines is segmentation, which means dividing the overall market (that is, everyone who flies or might fly) into smaller groups of people who are relatively homogeneous in terms of how they use a service. With this information, companies can identify which segments to address for any particular product as well as the best ways of marketing to them.

Segmentation on airplanes is very evident in the presence of economy, business, and premium classes of travel, which are physically separated from each other and with unmistakable evidence of deferential treatment available for different prices. However, there are more subtle ways in which this has been approached. The destination involved might provide a clue for how potential individual or group travelers might be approached, for example, in the case of Muslim travelers wishing to go to Mecca for the hajj or sports fans wishing to travel for a specific sporting occasion. People traveling for holidays might be willing to accept lower cost options at unpopular times of day, while business travelers might be willing to pay a premium (or have their companies pay it) to arrive and depart at more convenient times. The differing motives of people are likely to be seasonal in nature and will also change in time alongside changes in the external environment more generally, as some destinations gain popularity and others lose it.

Cost Leadership

The emergence of budget carriers with much greater latitude to establish their own networks under deregulated, open skies conditions has seen the rise to prominence of cost leadership as a dominant marketing strategy in the 21st century. Companies in this sector recognized the increasing number of people able and willing to fly either for the first time or on a more regular basis if low-cost flights were made available to them. To reduce costs, budget carriers stopped offering free in-flight entertainment and meals, charged passengers extra for checking luggage, and sweated the aircraft assets by increasing the average daily amount of flying time from around six-to-eight hours to as much as twice that. Rapid turnaround times and avoiding the use of land bridges are other operational approaches to lowering costs, and the application of science has also been used through research into paint technology so as to save some money by using lighter coatings.

These flights have certainly been very popular and have helped create new sectors of the market; for example, flights from the United Kingdom to low-cost Baltic destinations have become popular for the stag weekends that groups of young (usually) men take before one of them marries. However, there has been some contestation of the practices in terms of the quality of service, notably, the distance from the supposed destination that the alternative airport might actually be and the impact on destinations that the new trade has caused. It is also the case that aircraft flights are very damaging to the environment in terms of both emissions and the physical impact on land cover caused by the transportation infrastructure required. There is, consequently, a tension between the desire for people to join in the international tourism industry and the long-term societal need for reduction in burning carbon-rich materials.

Competition

The September 11, 2001, terrorist attacks in the United States led to the grounding of aircraft in many parts of the world and, as a minor consequence, led people to reevaluate their need to be physically present in a specific location to conduct business negotiations. Video conferencing technology, combined with breakthroughs in the Internet and mobile telecommunications, has come to represent a significantly important alternative to regular air travel. Further, increasing awareness of

the environmental damage caused by air travel and the importance of local productions also represent forms of competition to airlines, which have yet to formulate new marketing strategies in response other than to seek out new market sectors.

Airline Passengers

America's first commercial airline flight took place in 1914, and passenger airline services on a regional basis began to develop in the mid-1920s. In 1929, 173,405 Americans took advantage of the growing services, most of them businessmen at the upper level. After 1945, the airlines began to compete with bus and rail services for passengers, and by the end of the 20th century, 50 percent of Americans were taking at least one round-trip flight a year.

Passengers require reservation and record management. For much of the history of commercial flight, such records were kept manually using record books, reservation cards, and other printed media, but a computerized system was introduced in the 1960s. In the 21st century, information is maintained by a network of computer reservations systems accessible by multiple airlines and travel agents, and paper tickets, in use since the first passenger flights, have yielded to electronic tickets.

In 1926, the first year the U.S. government compiled data on the airline industry, 6,000 passengers flew 1 million passenger miles at a cost of \$1.59 per mile (adjusted for inflation). In 2012, more than

8 million passengers flew over a billion passenger miles at a cost of 11.3 cents per mile. Yet many of those millions in 2012 were unhappy passengers. They filed 11,445 complaints with the U.S. Department of Transportation in 2012, an increase of more than one-fifth from the previous year. The rate of complaints per 100,000 passengers also rose, from 1.19 in 2011 to 1.43 in 2012.

This season of passenger discontent comes after the U.S. Department of Transportation implemented new passenger protections in 2009 and 2011. The changes in 2009 dealt with lengthy delays after passengers were on the plane. The regulations prohibited U.S. airlines operating domestic flights from permitting an aircraft to remain on the tarmac for more than three hours without deplaning passengers. Exceptions are permitted for safety or security. The airlines are also required to provide passengers with food and potable drinking water within two hours of delays and to provide access to lavatories and medical attention, if needed.

The first airline consumer protection rule brought significant improvement in the airlines' record of delays, with the largest U.S. airlines reporting only 16 tarmac delays of more than three hours during the first 10 months the regulations were in effect, compared to 664 extended delays during the previous 10 months. The regulations implemented in 2011 expanded the ban on tarmac delays, required reimbursement for lost baggage, increased compensation for customers involuntarily bumped from flights, and mandated disclosure of hidden fees. Despite these changes, shrinking seat size and overbooked flights ensure disgruntled passengers.

Reservations

As air travel became a favored mode of transportation for more people, reservation systems became essential. Early systems utilized cards organized by departure date and stored in tubs that moved from one reservation agent to another as needed. These manually processed reservations could be made only 30 days in advance of departure, and each airline maintained its own system. A single reservation transaction could take as long as two hours, and even when efficiency improved, the average transaction consumed 45 minutes. This procedure continued largely unchanged until the Semi-Automated Business Research Environment (SABRE) revolutionized the reservation system in the 1960s.

SABRE was proprietary to American Airlines, but other airlines soon launched their own computerized systems. Delta introduced DATAS (Delta Automated Travel Account System) in 1968, and United followed with its Apollo system in 1971. The proprietary systems began granting access to travel agents and after deregulation evolved into multi-airline distribution systems, or global distribution systems (GDSs), which functioned independently of airlines. Most reservations made through a travel agent, whether in physical travel agencies or online, go through a GDS. Airlines now pay the GDS a fee of around \$12 for each round trip booked, fees that total \$7 billion a year. The efforts of airlines to avoid these fees by having passengers make reservations directly through the airlines have met with limited success. If the common technical standard for direct-connect services proposed by the International Air Transport Association (IATA) in November 2012 is adopted, travel agents and passengers may bypass the GDS and make reservations directly through the Web sites of airlines.

Tickets

Airline tickets were introduced in 1909 with the earliest passenger flights. For most of the history of passenger flight, "ticket" referred to a paper confirmation that a person had purchased a seat on a flight on an aircraft. Depending upon the source, the first electronic ticket for airline passengers was offered by Atlanta-based, low-cost ValuJet in 1993 or by Southwest Airlines in 1994. By the end of the decade, more than half of all airline tickets were paperless. Before 2008, the year set by IATA for a full transition to e-tickets worldwide, 97 percent of tickets sold in the United States were electronic.

E-tickets have distinct advantages for passengers and for airlines. They cannot be lost since they exist in a computer database network and can be easily replaced if a printout is misplaced, and they are more difficult to steal since only a person with the proper identification can use the ticket. Paper tickets are more complicated to replace, and replacement sometimes requires additional charges. E-tickets make it easier for airlines to contact customers about changes or cancellations and to process refunds more quickly.

Full conversion to e-tickets would save airlines an estimated \$3 billion annually. Using e-tickets is also environmentally responsible because,

according to an IATA estimate, if e-tickets were used exclusively, the industry would save the equivalent of 50,000 mature trees each year, about 3 square miles of forest.

E-tickets are saving time, labor, traveler frustration, and trees, but they are not saving money for passengers. In 2011, domestic fares rose by an average of 8.3 percent over the previous year and increased another 3.1 percent in the first nine months of 2012, according to the U.S. Department of Transportation's Bureau of Transportation Statistics. Still, more passengers buy tickets. The Bureau of Transportation Statistics reported that 815.3 million scheduled passengers traveled on U.S. airlines and on foreign airlines serving the United States in 2012, a 1.3 percent increase from 2011.

negotiated a government contract to deliver mail, establishing a pattern of cooperation between government and the airlines. Labor unions were virtually nonexistent in those early years, consisting only of the Airline Pilots Association (ALPA). As the industry expanded to meet increased commercial demands, labor issues increasingly demanded attention. Until the late 1950s, U.S. government officials left most labor issues to airline industry officials. Collective bargaining issues were regulated by a 1936 extension to the Railway Labor Act of 1926. As a result, the Civil Aeronautics Board (CAB) was allowed to set airline fares and establish the routes that each airline could fly. Because of stipulations in the original act, negotiating contracts could be a lengthy process. Throughout contemporary history, labor problems in the airline industry have been heightened by deregulation, bankruptcies, mergers, and widespread economic downturns.

An Evolving Industry

In 1958, the payroll for the airline industry was \$800 million, comprising 41 percent of total industry expenses. During that year, there were 15 strikes that lasted from one half day at Eastern to 108 days at Western. The main contentions involved higher wages for pilots and crews, job security, and jurisdictional disputes between pilots and flight engineers. As tensions heightened, President Dwight D. Eisenhower established Emergency Board Number 123 to serve as mediator. By the end of the decade, the number of unions had grown to 31, representing some 49,000 employees. The three largest unions were the International Association of Machinists with 27,913 members, the Transport Workers Union with 15,354 members, and the Airline Pilots Association with 14,354 members.

The Airline Stewardesses Association, the first flight attendants' union, was established in 1945 by stewardesses at United Airlines. The following year, the Airline Stewards and Stewardesses Association was established as a rival union under the auspices of the Airline Pilots Association. Early concerns focused on increasing wages, improving working conditions, and winning the right to redress grievances. The two unions merged in 1949, but women were often unhappy with the male-dominated leadership, and infighting was common. Beginning

Airline Pilots and Crews, Labor Issues of

Aircraft came into their own during World War I, and commercial airlines began establishing themselves in the years after the war. In 1926, Colonel Lewis Brittin founded Northwest Airlines and

Flight attendants on a Russian Aeroflot Sukhoi Superjet 100 aircraft in November 2011 point out the emergency exits to passengers during their onboard safety demonstration.

in the 1960s, the women's movement had a major impact on how flight attendants dealt with labor concerns as they battled against weight, marriage, maternity, and age restrictions. By 1974, the union had become the Association of Flight Attendants, an autonomous affiliate of the ALPA.

Deregulation and Bankruptcies

Within the airline industry, the major event of the 1970s was deregulation. Passed by Congress in 1978 and signed into law by President Jimmy Carter, passage of the Airline Deregulation Act meant that the industry no longer had to seek government approval to add or withdraw domestic routes. Consequently, competition among the airlines increased significantly. In 1977, President Carter appointed Alfred Kahn as head of the CAB, and Kahn launched a campaign to deregulate the industry. Kahn gained support by demonstrating that unregulated flights inside each state were cheaper proportionally than interstate flights that were the subject of federal regulation. Deregulation and greater competition did result in reduced fares for customers, but they

also led to lower wages and declining working conditions for airline industry employees.

One of the major labor issues of the 1980s involved the number of pilots required to fly jetliners such as the Boeing 737 twinjet and the McDonnell Douglas DC-9 Super 80: the pilot's union insisted that safety called for three pilots, but management and the Federal Aviation Administration (FAA) insisted that only two pilots were needed. A presidential task force ultimately upheld the FAA's decision, agreeing that the use of two rather than three pilots did not impair safety.

In the 1990s, Northwest, the oldest American airline still in operation, began to be known as "North-worst" because of its record of poor customer service and delays in flights. Pilots at the airline expressed dissatisfaction with issues related to wages, job security, retirement benefits, per diem allowances, and profit sharing. As a result, tensions continued to mount. In 1993, the American Airlines flight attendants union chose to strike during the Thanksgiving season, leaving scores of travelers stranded. When the Allied Pilots Association initiated a strike in February 1997, President Bill Clinton responded by instituting the mandated 60-day cooling-off period allowed by the Railway Labor Act of 1926, which forced strikers to return to their jobs while negotiations were under way.

In a December 1, 2011, article written for *Slate*, Matthew Yglesias reported that throughout its history, American passenger aviation had generated cumulative earnings of negative \$33 billion. Between 1990 and 2011, the airline industry filed 189 bankruptcy petitions. Most of those filings were the result of major disputes with labor unions.

Twenty-First-Century Issues

In the early years of the 21st century, airline labor problems continued to mount, involving pilots, flight attendants, ground crews, and other employees involved in negotiating new contracts. Because a number of airlines had been pushed to the brink of collapse, many employees had not had a raise since the turn of the century. Problems grew so intense in the summer of 2012 that journalists dubbed it "the summer of discontent." Employees at United, which had merged with Continental, were unsettled because of the failure to reach agreements with its major labor groups, and employees at Continental were waging

protests and discussing a possible strike. Southwest announced plans to begin outsourcing jobs to temporary workers. The Association of Professional Flight Attendants expressed general dissatisfaction with current working conditions.

Economic problems have frequently been accelerated by labor and mechanical problems, particularly in the case of airlines struggling to stay afloat. In September 2012, flight delays and cancellations resulted in a 4 percent loss for bankrupt American Airlines. That loss led to a 6 percent cut in domestic flights. Other airlines also continued to lose a portion of their customer base: Delta's passenger count fell by 1.9 percent, United's by 2 percent, and Southwest's by 2.6 percent during that same month.

As 2012 drew to a close, United and its pilots finally signed a contract after two years of labor tensions. However, tensions with maintenance crews continued. In November, United suspended a pilot who had delayed a flight by insisting on changing a slashed tire due to safety concerns. United blamed maintenance labor problems for the vast majority of delayed and scrubbed flights. United's flight attendants also continued to press for a wage increase.

For most airlines, keeping labor costs manageable is essential to remaining in business. Labor issues frequently inconvenience customers, but maintaining safety and customer satisfaction must necessarily remain top priorities for both employees and management.

Airline Service Quality Modeling

Quality of service index (QSI) models are used to estimate market shares and passenger volumes. QSI models were developed by the U.S. government in 1957 and were used during the regulation era to evaluate carriers' requests to increase fares on specific routes. The first QSI models allocated demand across different routes as a function of three service quality attributes: aircraft equipment type, number of stops, and flight frequency.

After airline deregulation in 1978, the definition of service quality was expanded to include other attributes, such as the departure and/or arrival times, departure day of week, connection times, code shares, average fares, and carrier (or brand) preference. The inclusion of these attributes enables carriers and route analysts to examine the following types of questions: How do mergers and acquisitions impact carriers' profitability and average fares paid by consumers? How does the presence of one or more low-cost carriers on a route impact passenger volumes, revenues, and profitability? Which flights should be marketed as code-share flights in order to maximize revenue? Which routes become

unprofitable to serve when fuel costs increase? How will reducing connection times increase passenger volumes and revenues? How will introducing a new aircraft that can travel farther or fly faster benefit airlines and consumers? How many and what types of aircraft should a carrier purchase? Should a carrier increase service at an existing hub? Should a carrier add flights to an existing market? Should a carrier introduce new nonstop service in a market?

Estimation of QSI Models

QSI models predict the impact of service level changes by calculating an index for each itinerary on a route. The QSI index for an itinerary is given as the product of coefficients (β) and itinerary attributes. The coefficients provide information on how customers value schedule attributes. For example, a large negative coefficient associated with connection time indicates that passengers prefer shorter connections and are willing to pay more to avoid long connections.

QSI coefficients are obtained using data sets that provide information about the schedules offered and which itineraries passengers purchased. Schedule information is typically easy to obtain and accurate. In contrast, passenger information is often difficult (or impossible) to obtain and may be incomplete and/or biased. Although carriers collect detailed information about their own customers' purchases, they have limited information about their competitors' customers. Historically, information about competitors' customers was obtained from commercially available passenger databases compiled by computerized reservation systems (or CRSs).

In the past, CRS data provided useful market share information because the majority of customers made their airline reservations by calling travel agents, who used the CRSs. However, Internet bookings and carrier-direct bookings (such as those made via the airline's phone reservation system) are not captured in this database, and the reliability and usefulness of this data set has deteriorated. Today, the CRS data is highly biased toward business travelers, who have different price sensitivities and schedule preferences from leisure travelers.

Within the United States, carriers have been able to use alternative databases to estimate QSI coefficients. These databases, which are commonly referred to as the DB1A and DB1B data sets, refer to the Origin and Destination Data Bank 1A or Data

Bank 1B databases that are maintained by the U.S. Department of Transportation. These databases are based on a 10 percent sample of flown tickets collected from passengers as they board an aircraft operated by U.S. airlines. The CRS database, as well as the DB1A and the DB1B databases, contain average monthly or quarterly price information. The lack of detailed pricing information limits the ability to use QSI models to understand the impact of prices on customer choices. For these reasons, there has been increasing interest in exploring alternative data sources for estimating the coefficients of QSI models, particularly among non-U.S. carriers.

Alternatives to QSI Models

Other models, namely those based on discrete choice models, have also been used to allocate demand across itineraries. Discrete choice models are conceptually appealing because they can incorporate different competition patterns among itineraries. For example, a discrete choice model is able to incorporate increased competition among itineraries that depart at similar times of the day. Thus, if a carrier introduces a new nonstop flight at 8 A.M., a discrete choice model would predict that this new itinerary would draw more passengers from nonstop flights departing in the morning than from nonstop flights departing in the evening.

A major U.S. airline published a study that compared demand forecasts produced from QSI and discrete choice models. This study found that the discrete choice model forecasts were consistently superior to those of the QSI model, with the magnitude of errors reduced on the order of 10 to 15 percent. In practice, however, the QSI model is often preferred over the discrete choice model due to its perceived ease of implementation.

Airplane Disasters

Since the advent of powered flight, airplane accidents and incidents have been part of civil aviation. Accidents, in fact, are expected, given that manned flight is dependent on man-made equipment operated by humans. The room for error and malfunction is great. Air enthusiasts quickly point out that, statistically, air travel is safer than automobile travel. A U.S. Department of Transportation statistical comparison of accidental deaths between 1999 and 2003 reports an average of 138 air accident deaths per year, compared to 36,676 motor vehicle deaths. Those numbers make the odds of dying in an air accident 1 out of 2.067 million, compared to 1 out of 7,700 for automobile deaths. Nevertheless, the dramatic nature of air accidents, the ability of 21st-century digital media to capture images of catastrophic accidents, and the fact that air accidents can kill hundreds of people in one incident make them especially frightening to the public. The following is a look at some of the deadliest or most notable and influential air accidents.

The First Air Fatality

Even people with little knowledge of aviation history know that Wilbur and Orville Wright, two American bicycle repairmen, inventors, and entrepreneurs, invented the first successful powered aircraft. Their first flight came in 1903 at Kitty Hawk in the Kill Devil Hills along the beaches of North Carolina. People may not know, however, that Orville Wright was also involved in the first fatal air accident.

The Wright brothers spent much of their time after perfecting the Wright Flyer trying to sell it to the U.S. Army. The Army would not consider a contract for airplanes unless the Wrights could prove their flyers could carry more than one passenger. At Fort Myer, Virginia, in 1908, the Wrights began a series of demonstrations to prove just that. Orville successfully flew Lieutenant Frank Lahm on September 10, then Major George Squier on September 12. On September 17, Lieutenant Thomas Selfridge, a member of the Army board assessing the aircraft, went up with Orville. During the flight, however, one of the Flyer's two propellers fell away. The plane was essentially a powered version of the cloth and wood gliders the Wrights had flown at the start of their experimental flights, and Orville tried to glide the crippled craft down.

The plane's weight characteristics, with a faltering engine and a passenger, were different from a glider's, however, and Orville could not get it under control. It crashed nearly nose first into the ground before a crowd of 2,000 people. Both Orville Wright and Lieutenant Selfridge were trapped under the wreckage of the flyer. Spectators pulled both men alive from the crash, but Selfridge died later that day of a skull fracture. Wright suffered leg, hip, and rib fractures. Selfridge, the first fatality of the aviation era, is buried in Arlington National Cemetery outside Washington, D.C.

First Commercial Air Accidents

The first commercial air accidents occurred soon after the end of World War I. The war had served as a school for many pilots who sought to make a living from the skill in peacetime. On August 2, 1919, two former Italian military pilots took off from Venice, Italy, in a Caproni Ca. 48, a tri-wing wartime bomber converted to carry passengers. Records are inconsistent, but from 12 to 15 passengers were aboard. At about 3,000 feet, the plane's ungainly wings buckled and collapsed. Some of the passengers tried to

U.S. National Transportation Safety Board investigators walk toward the charred fuselage of Asiana Airlines Flight 214 in San Francisco, California, the day after it crashed on landing after a flight from Incheon, South Korea, on July 6, 2013. The crash led to the deaths of three passengers and 181 injuries. As with many crashes, the aftermath drew attention to potential improvements to be made to safety features, as two evacuation slides deployed inside the aircraft and temporarily trapped flight attendants within.

escape by jumping from the passenger compartment, but everyone died in the crash.

Four people died in December 1920 when an aircraft crashed on takeoff at a London airfield. No air deaths were recorded in 1921, making that the last year in which no air fatalities occurred.

The next year, 1922, saw the first mid-air collision of two airliners. The pilots of a de Havilland DH.18A and a Farman F.60 Goliath were flying in bad weather, and both were using roads on the ground near Picardie, France, as navigational aids. Everyone on both planes, seven people in all, died in the crash. The crash prompted the codification of distinct air routes in Europe, the installation of radios in air transports, and the rule that pilots must stay to the right when encountering other aircraft.

Single Worst Air Disaster

History's single worst air disaster occurred March 27, 1977, at Los Rodeos Airport on Tenerife Island in the Canary Islands. The accident was the culmination of many disruptive events.

Two passenger aircraft, a Dutch KLM 747 and an American Pan Am 747 were among many diverted that day from nearby Gran Canaria Island airport, where a separatist (who wanted Canary independence from Spain) had set off a bomb earlier that Sunday. As the planes waited for clearance to leave Tenerife, the weather changed, and a dense fog covered the airfield.

Shortly after 1 P.M. the planes received permission from air traffic controllers to begin taxiing into takeoff positions. Air controllers, however, had no ground radar, and the fog limited their vision as well as that of the pilots on the jets. Recordings of radio traffic between the planes and the tower revealed confusion in the conversation between all the people involved. In the confusion, both 747s wound up heading toward each other on the same runway. The Pan Am craft was taxiing, but the KLM plane was gathering speed for takeoff.

The Pan Am crew saw the KLM plane's landing lights pierce the fog, then realized the plane was barreling down on them at nearly 160 miles per

hour. The Pan Am's pilot tried to make a left turn off the runway and onto the grass. Amid a flurry of cursing on the radio, the KLM crew rolled back their controls and tried to take off over the Pan Am plane. The KLM pilot threw his plane into such a steep attitude that its tail threw sparks as it dragged the runway.

The maneuver was not enough. The KLM's landing gear struck the upper starboard side of the Pan Am plane and its two right-side engines tore through its fuselage. Then it climbed about 100 feet before it crashed. The KLM's full fuel tanks ruptured and exploded. All 248 people on the KLM flight died. On the Pan Am aircraft, 335 people died, but 61 survived.

The disaster prompted a review of international airport procedures. The review immediately mandated uniform language between aircraft and air traffic controllers, as well as the practice of aircraft crew members repeating critical portions of controllers' instructions.

The 1977 crash was not the only major accident at Tenerife. A few years earlier, on December 3, 1972, a Convair CV-990 operated by Span-tax climbed about 300 feet off the runway, lost control, and crashed, killing 155 people. Like the KLM–Pan Am crash in 1977, the Convair accident occurred in low visibility.

On April 25, 1980, yet another plane went down near Tenerife killing all aboard. The plane, a Boeing 727 operated by Dan-Air, was in a circular holding pattern above high ground near the airport. The crew, however, had not reported their position, and they were too low to safely navigate the mountainous area. The plane crashed into Mt. La Esperanza, and 146 people died.

Grand Canyon Disaster

On June 30, 1956, a Trans World Airlines (TWA) Lockheed Constellation and a United Airlines DC-7—both four-engine, propeller-driven aircraft (the Constellation with a distinctive tri-rudder design)—left Los Angeles International Airport within three minutes of each other: TWA Flight 2 bound for Kansas City, and United Flight 718 for Chicago. The TWA plane flew at 19,000 feet, and the United aircraft was 2,000 feet above it at 21,000 feet.

As both aircraft neared the Grand Canyon, they flew into rough weather and clouds. The captain of TWA 2 requested permission to climb to 21,000 feet,

but air traffic controllers denied the request, given that United 718 was at the same altitude. The TWA captain then asked to get 1,000 feet above the clouds and go on visual flight rules (VFR). Air traffic control assumed that both aircraft would then be able to see each other. Incredibly, with both planes on VFR, air controllers had no further responsibility to watch the craft. At about 10:30 A.M., the planes collided over the Grand Canyon. The United DC-7 hit the TWA Constellation's tail, and DC-7's propellers ripped open the Constellation's body. The Constellation's tail severed and began to fall; the front of the plane dived nose first into the canyon. The United flight also plummeted, hitting the top of a nearby mesa; 128 people died.

The Grand Canyon disaster prompted a massive \$250 million overhaul of the nation's air traffic control system. The federal government also responded with the creation of the Federal Aviation Administration (FAA).

Japan Airlines Flight 123

On August 12, 1985, Japan Airlines (JAL) Flight 123 suffered an explosive decompression 12 minutes after takeoff from Tokyo International Airport when the fuselage of the 747 ruptured near the tail. The explosion severed electrical and hydraulic lines, rendering the plane uncontrollable. Pilots attempted to steer the jet toward a safe landing by using variable engine speeds, but that maneuver also failed.

Some 32 minutes after the explosion, the 747 crashed into and slid down Osutaka Ridge. Only four people survived the crash—520 others perished. That made the crash the deadliest single-aircraft disaster, and the second-deadliest crash behind the 1977 Tenerife incident.

Investigators discovered that the JAL 747 had been involved in a tailstrike incident (that is, the tail struck the runway when the plane was at too steep an angle) in 1978. The tailstrike damaged the upper fuselage near the tail. The damage was not repaired properly. It was the same area of the fuselage that failed in 1985.

The End of Supersonic Transport

Since the 1960s, England and France had flown Concorde Supersonic Transports (SSTs) as passenger airlines. In 1985, one famously flew pop star Phil Collins from a Live Aid concert in Europe to a sister concert in the United States in one day.

Supersonic passenger transport ended, however, on July 25, 2000, when an Air France Concorde taking off from Charles de Gaulle Airport hit some debris on the runway. A tire burst, and more debris punctured a wing fuel tank. The plane erupted in flames. The Concorde rose briefly, then it crashed into a hotel. The accident killed 109 people on the plane and four people on the ground. Concorde's were already being retired at the time of the accident, which permanently grounded the remaining supersonic craft.

Terrorism

Airliners have been a frequent target—or weapon, in the case of the 9/11 attacks in the United States—of terrorists.

On September 11, 2001, terrorists of the al-Qaeda terrorist organization hijacked four U.S. airliners and used them to target the World Trade Center in New York City, the Pentagon in Washington, D.C., and another target, unconfirmed but believed to be in the capital area.

The terrorists commandeered American Airlines Flight 11 and United Airlines Flight 175 and flew them into the Twin Towers of the World Trade Center, their fuel supplies igniting and causing fires that eventually buckled the towers, causing their collapse. Another terrorist group took over American Airlines Flight 77 and flew into the Pentagon. Still another terrorist band skyjacked United Flight 93, but passengers attacked them and forced the airliner down in a field near Shanksville, Pennsylvania, before they could reach their intended target. A total of 265 passengers and crew died on the aircraft. Another 2,731 people died in the World Trade Center and Pentagon.

In another of the most infamous terrorist aircraft incidents, Libyan terrorists planted a bomb on Pan Am Flight 103. On December 21, 1988, it exploded, bringing the 747 down near Lockerbie, Scotland. The incident killed 270 people, including 11 on the ground. Libyan dictator Muammar Gaddafi later admitted Libyan responsibility for the attack.

By the Numbers

An article of this length cannot possibly describe all the major accidents of the aviation age. To sum up, however, the following have been of note:

- Two accidents that killed more than 500 people (not including the 9/11 attacks in the United States)
- Four accidents that killed more than 300 people
- Twenty-two accidents that killed more than 200 people
- Seventy accidents in the top 100 worst aviation accidents that killed more than 100 people

Airplane Navigation Systems

The principle of airplane navigation is simple. Air navigation differs from surface navigation in that aircraft travel at relatively high speeds, thereby reducing the time to calculate their position en route. Additionally, aircraft are safety-limited by fuel capacity, and in-flight collisions with other

aircraft or terrain are usually fatal. As such, airplane navigation systems are critical to the safety of flight. The airplane navigation systems used for visual flight rules (VFR) and instrument flight rules (IFR) will vary. In the latter scenario, pilots navigate almost exclusively using the aircraft's navigation systems to ensure compliance with air traffic control.

Many aircraft are equipped with a variety of navigation systems, such as compass, automatic direction finder (ADF), inertial navigation systems (INS), flight management system (FMS), VHF Omnidirectional range (VOR), tactical air navigation (TACAN), VHF omnidirectional range/tactical air navigation (VORTAC), radar navigation, global navigation satellite systems (GNSS), instrument landing system (ILS), microwave landing system (MLS), and localizer directional aid (LDA).

Types

The magnetic compass displays the aircraft's current magnetic heading: the aircraft's direction of travel relative to the globe's magnetic field. At the Earth's poles, magnetic compasses are unreliable. Further complicating polar navigation are converging meridians at the poles. A type of navigation called grid navigation is typically used in place of magnetic navigation when flying over the polar regions. With grid navigation, a separate grid system is applied over the polar regions to aid in navigation.

Radio transmitters, commonly referred to as nondirectional beacons (NDBs), are the radio equivalent of a lighthouse. These beacons send out an amplitude modulation (AM) radio signal. The signal itself does not include a direction. However, equipped with an automatic direction finder, the aircraft can locate the direction of a radio source; the ADF automatically and continually displays the relative bearing from the aircraft to a radio station. The effective range of these beacons varies from 15 to 75 nautical miles, depending on the transmission power of the beacon.

VOR is another type of ground navigational aid using short-range radio navigation. VOR enables an aircraft to determine its position and maintain course by receiving radio signals from a network of ground beacons. The bearing is displayed in the aircraft. The line of position is the "radial" from the VOR. The intersection of radials from two different

VOR stations on a chart provides the aircraft position. VOR stations have a relatively short range, typically 200 miles or less.

TACAN is a navigation system used by military aircraft that provides the aircraft with bearing and distance, known as "slant-range" to a ground or ship-based station. It is a more accurate version of the civilian VOR/DME system. The DME (distance measuring equipment) portion of a TACAN is available for civilian use at VORTAC stations where VOR is combined with TACAN to provide VOR/DME information. Distance from the station is provided by measuring the time required for the signal exchange from the station to the aircraft. Aircraft equipped with TACAN can use this system for en route navigation and nonprecision approach landings.

Variations of the ADF/VOR/TACAN and VORTAC displays include horizontal situation indicators (HSIs), radio-magnetic indicators (RMIs), and bearing-distance-heading indicators (BDHIs), all of which overlay bearing information onto a compass card to display relative bearing to a radio source with respect to the aircraft's heading.

Inertial navigation systems work by providing a computer with the aircraft's present position. Accelerometers and gyroscopes measuring changes in acceleration and direction provide data to the computer. This data is then used to constantly measure and recompute changes in speed and direction to provide an accurate estimation of the aircraft's present position.

Over long distances, inertial navigation systems can accrue small amounts of error. This error can be corrected by taking a fix and updating the present position of the inertial navigation system in flight. The data from inertial navigation systems can also be combined by aircraft computers with other navigation systems, such as global navigation satellite systems, to obtain a blended, more accurate navigation position.

Many newer aircraft are equipped with a flight management system (FMS) consisting of a flight management computer (FMC) and one or more control display units (CDUs), and an internal navigation database. The FMS utilizes aircraft sensors and the navigation database to compute and display aircraft position, performance data, and navigation information during all phases of flight. The navigation database usually contains regional or

worldwide coverage and typically includes information on navigation aids, airports, runways, waypoints, routes, airways, intersections, departures, arrivals, and instrument approaches. Navigation databases require periodic updates to ensure the data are current.

With radar navigation, the aircraft sends a pulse of microwave energy and the energy is reflected by objects in its path. Pulse is amplified and converted by a receiver using a cathode-ray tube (CRT). Additional features have been added such as weather avoidance and terrain following. The radar produces an image of terrain and man-made features such as cities with respect to aircraft position, which can be used to generate a visual navigation aid. Radar can be used for both en route navigation and approaches.

Global navigation satellite systems (GNSS), more commonly known as global positioning systems (GPS), use a system of space-based satellites to provide highly accurate three dimensional position, velocity, and time to aircraft. GNSS/GPS can be used for both en route navigation and landing approaches.

Instrument landing systems provide an approach path alignment and descent to the final approach of a runway. The ground equipment consists of two highly directional transmitting systems, optional DME transmitters, and marker beacons or compass locators. The directional transmitters are known as the localizer and the glide slope is displayed on the cockpit instrument panel(s).

Microwave landing systems provide precision navigation guidance for exact aircraft alignment and descent during approach to a runway by integrating azimuth, elevation angle, and range (DME) information to provide precise aircraft positioning. Similar to an ILS, MLSs use an elevation station instead of glide slope antennas, and instead of a localizer antenna MLSs use an azimuth station.

Localizer directional aids are similar to localizers (LOC) except that they are not always aligned with the center of the runway. Terminal instrument procedures (TERPs) requires localizer signals to be within 3 degrees of the runway alignment. If this alignment exceeds 3 degrees, the localizer is identified as a localizer directional aid. Generally, LDAs are considered nonprecision approaches unless additional information is published. Note:

LOCs/LDAs are abbreviated LLZs by the International Civil Aviation Organization (ICAO).

Airplane Pilot Licensing

In the early history of flight, there were no regulations, and pilots flew without licenses. Neither planes nor flight schools were certified, and those interested in learning to fly could do so for around \$100. The Air Commerce Act of 1926 required aircraft to be inspected and those who flew them to be tested for aeronautical knowledge and physical fitness. By October 1928, 3,659 licenses had been issued in three categories: air transport, industrial, and private. The highest level required only 100 hours of solo flight. More than three-quarters of a century later, according to the Federal Aviation Administration (FAA), there are more than 618,000 certified pilots in the United States. Air Transport Pilot certification requires a minimum of 1,500 hours as a pilot.

The Beginning of Licensed Pilots

William P. MacCracken, Jr., assistant secretary of commerce for aeronautics, received the first pilot's

license issued by a civilian agency of the U.S. government on April 6, 1927. Orville Wright refused the honor, saying that he no longer flew and indicating that a federal license was unnecessary to show that he had been the first man to fly. Unlicensed pilots were given until May 1, 1927, to apply for a license. The new air regulations stated that after that date it would be illegal to fly “any aircraft registered as an aircraft of the United States” without a certificate. Charles Lindbergh was issued license no. 69 in time for his historic solo flight across the Atlantic on May 20–21, 1927. Phoebe Fairgrave Omlie received transport license no. 199 on June 30, 1927, probably the first woman granted a pilot license by a civilian agency of the U.S. government.

MacCracken was licensed as a private pilot. Although he had experience as an Army pilot in World War I, regulations required only 10 hours of solo flight, two of which must have been within 60 days immediately preceding application, to license a private pilot. Air transport pilots were initially required to have 100 hours of solo flight, double the number required of industrial pilots, and to pass a physical examination every six months, but within five years, technological advances led to new requirements. On May 16, 1932, the official *Air Commerce Bulletin* announced that, effective January 1, 1933, all pilots on scheduled interstate passenger service must secure a new rating for transport pilots. The new rating would be awarded only after pilots demonstrated their ability to use airway navigation aids and to fly specified maneuvers guided entirely by instruments. By the end of 1932, 330 pilots had received the new rating. Fifty years later, the estimated number of certified airline transport pilots was 73,741.

Pilot Training

Some pilots receive their training from accredited, degree-granting, postsecondary institutions that range from technical schools to universities. For example, students at top-ranked Embry-Riddle Aeronautical University, which offers 35 degrees, including a Ph.D. in aviation, pay more than \$30,000 a year to attend the largest and oldest aviation school in the world. Some pilots receive their training while in the military, but most pilots are trained by flight instructors at flight schools approved by the FAA where basic flying lessons, ground instruction, and related fees run around \$10,000.

FAA-approved flight schools fall in two categories based on the part of FAA regulations under which they operate. Part 61 schools have greater flexibility. Instructors are not required to follow a syllabus. They must cover material specified by the FAA, but they are free to do so based on student progress. Students in these schools are not required to complete a formal ground school program, although they must pass the written and practical examinations required by the FAA. Part 141 schools are more structured, operating under an FAA-approved syllabus that is adhered to throughout training. Students are required to complete a specified number of hours of ground instruction in a classroom setting or individually with a flight instructor. The FAA requires students in Part 61 schools to have a minimum of 40 flight hours to receive certification as a private pilot and students in Part 141 schools to have a minimum of 35 hours. Since the national average for initial certification as a private pilot is 65 to 70 hours, this difference is insignificant. A difference exists in flight hours to be certified as a commercial pilot as well. Part 61 schools require a minimum of 250 hours, whereas Part 141 schools require only 190 hours.

Pilot Certification

The FAA has the authority to grant pilot certificates in six categories. “Certificate” is the word used in the official authorization, but “license” is used informally and interchangeably. The categories include student pilot, recreational pilot, sport pilot, private pilot, commercial pilot, and airline transport pilot. On certificates other than student pilot, ratings are specified as the individual completes training and certification requirements in such areas as aircraft category (airplane, rotocraft, glider, etc.), airplane class (single-engine land, single-engine sea, multi-engine land, multiengine sea), and instrument (for private and commercial planes).

Although a student pilot certificate is not required to take flying lessons, any individual who flies solo must have a valid student license. The only requirements are that an individual be at least 16 years old (14 years old for a glider or balloon); read, speak, and understand English (required for all certificates); and hold at least a current third-class medical certificate. A third-class medical certificate affirms that the applicant has the vision, hearing, and general physical condition to operate an aircraft safely and is free of mental disorders

and substance dependence. Both the student pilot certificate and the medical certificate are valid for 60 months, for those under 40 years of age, and 24 months for those over 40 years of age.

The Sport Pilot Certificate, the only one that does not require a medical certificate, was created in September 2004 to license those interested in flying light sport aircraft. A sport pilot may exercise flight privileges in one or more of the following: single-engine airplanes, gliders, airships or balloons, gyroplanes, powered parachutes, or weight shift control aircraft. He/she must be at least 17 years of age and log a minimum of 20 hours of flight time: 15 of dual instruction with a qualified instructor, two cross-country dual instruction flights, and five solo flights. This category is growing in popularity at the cost of recreational pilots. In 2011, 4,350 sport pilots held active certificates, compared to 210 recreational pilots.

There were 195,650 certified private pilots in the United States in 2011. Depending on the ratings acquired, private pilots can fly almost any plane under visual flight rules for any noncommercial purpose. In addition to the standard requirements of command of English, medical certificate, and written examination of knowledge and actual flight, the private pilot, who must be at least 17, must accumulate a minimum of flight hours with an instructor and solo. Part 61 training requires 40 hours (20 with an instructor and 10 solo); part 141 training requires a minimum of 35 hours (20 with an instructor and 5 solo). Both require night and cross-country flight to be included in the total.

To be granted a commercial pilot certificate, an individual must be 18 years old and hold a private pilot license and second-class medical certificate, which requires that all the criteria for a third-class certificate be met in addition to more stringent vision standards. Second-class medical certificates must be renewed annually. Flight requirements under Part 61 regulations include a minimum of 250 flight hours as pilot, with 30 hours accompanied by an instructor and 10 solo hours. Other flight requirements include specified amounts of day, night, and cross-country flight. Part 161 regulations specify a minimum of 190 hours, 55 hours with an instructor and 10 solo. As with other certificates, the applicant must pass both a written and a practical test.

To be eligible for an airline transport pilot certificate, the applicant must be 23 years of age, be of good moral character, hold a commercial pilot

license with an instrument rating, pass a stringent written and practical test, and have a minimum of 1,500 hours of flight time as a pilot. The required flight time must include 500 hours of cross-country, 100 hours of night flying or 75 hours plus 45 full-stop landings at night, and 75 hours of instrument flight time or 50 flight plus 25 simulator hours. The airline transport pilot must also hold a class one medical certificate, which requires the applicant to meet all criteria for third- and second-class certifications plus have an electrocardiogram that shows normal heart function.

Airplane Pilot Training

Pilot training is one of the paramount missions of the Federal Aviation Administration (FAA). Steady advances in technology, constant updating of aircraft-type instrumentation and airfield-layout databases, and continually improving user interfaces have led to near-universal dependence on flight simulators as an integral part of every pilot's training.

Flight simulators, with their capacity to economically and rapidly test the widest range of conditions and scenarios, are also an indispensable part of aircraft prototype development. Additionally, the analysis of pilot and airplane performance monitoring data is increasingly integrated into the ongoing evaluation of individual pilots and aviation companies; this in turn leads to improvements in

subsequent training. In essence, pilot training is a continually improving and updating process, and the FAA's role is central to its quality and reach.

Military Impetus

From the earliest days of machine-powered flight, flying enthusiasts have sought ways to share knowledge, test new designs, and refine approaches to piloting. At the same time, the quest to reduce accidents, fatalities or injuries, and property loss has been a constant. Rapid and sophisticated advances were made during World War II, as national governments provided the impetus, personnel, and funding for research and development of military combat and support aircraft flight training devices and procedures. Innovation led to the design of a variety of celestial navigation simulators as well, some so large they were constructed inside 45-foot-high silos, to provide crew training in nighttime navigation by the stars.

As other technologies related to aviation leaped ahead, the engineers crafting flight simulators had to keep pace and adopt appropriate mock-ups and stand-ins into their own designs. Radar research and development, for one example, led to the need for training devices that incorporated systems to simulate visual contact, enemy aircraft identification and apparent course, target acquisition and lock-on pathways, and other factors. In the United Kingdom, the use of synthetic radar trainers, as they were called, was estimated by the Royal Air Force to have saved as much as \$50 million in aviation fuel over the course of the war.

In the years following World War II, pressures to innovate were intense, and the momentum in flight simulator design and production, rather than slowing down, actually accelerated. Both military and commercial endeavors expanded at full speed all around the aviation sphere; the development of flight simulators grew along with this general burst of industrial aeronautical experimentation and enterprise.

As military aircraft grew in terms of size, mission distance, payload, and endurance capacity, the flight simulators also expanded and diversified. Many of these training units dropped the use of motion simulation in favor of a focus on the myriad newly developed electronic switches, controls, communications devices, and other systems that flight crews had to master. Human trainers became expert at inventing ways to simulate emergencies,

A U.S. Navy F/A-18 pilot training in a flight simulator at a naval air station in Lemoore, California. Flight simulator training can cost as little as 2 percent of the expense of training in aircraft.

whether derived from extreme weather, equipment malfunction, misunderstood commands, enemy actions, or other sources. The movements, decisions, and communications of the trainees were observed live and up close, typically through open-backed installations, via mirrors, or through frosted window glass.

The growth of civilian flight simulators also boomed during this period, with aviation manufacturer Curtiss–Wright taking the lead. The simulators from this production resource incorporated an enhanced measure of feedback in the sense that some of the instrumentation would respond or change appearance in reaction to the actions of the trainees. This type of improved feedback, along with the earliest real tri-axis cockpit movement simulation, became widely adopted by commercial aviation training instructors and flight schools.

These commercial aviation pioneers of simulator technology improved and invested in the “virtual

reality” of their eternally grounded equipment, as is the case today, because even with such major investment the cost was far below that of actual flight training in fuel-consuming and damage-risking airborne craft. Research has suggested that the use of flight simulators for training can yield a cost structure as little as one-fiftieth, or 2 percent, of the cost of using operating aircraft for flight training.

For its part, the FAA emphasizes the use of flight simulators in its goals for improved aviation safety in the United States, and for U.S.-based pilots specifically, through the activities of its National Simulator Program (NSP). This formalized structure provides standards for simulator device design and usage procedures, instructor and simulation manager qualifications, and various certification levels for trainees. The NSP also maintains a suite of international agreements on these and similar rules and standards in bilateral compacts with foreign-based companies and civil authorities.

Technological Advances

In the 1960s, the visual displays in flight simulators became more and more convincing; cockpit motion activation was also moving into the realm of the near-real. Use of projection and collimated (parallel-beam) light enhanced the depth perception aspect of the visual experience, while hydraulics blended axial motion into highly accurate mimicry of aircraft motion.

Furthermore, it was in this decade that computing power began to be unleashed into the field of flight simulator technology. This power enabled the crafting of a vast series of conditions, scenarios, and prototype alterations and the strongest visceral feedback yet achieved. It also gave instructors the ability to customize training sessions to the varied abilities and skill levels of the individual trainees. Instructors could monitor sessions more intimately, predict challenges and errors, and introduce test elements more in tune with the background experience and flight competency goals of many types of trainees.

As the 1970s dawned, engineers found ways to completely envelop the flight simulator trainee in an enclosed machine that exuded real aircraft sights, sounds, and motion—and that provided feedback to the trainee’s senses that was exactly close to what he or she would experience in the air. The instructor’s observational abilities, control

capacity, and reporting systems kept enlarging and improving as well, thanks to computer-aided interfaces and data streams.

Electric motion and control loading technology have, in the decades since then, in many cases replaced the use of hydraulics in flight simulators. Attendant savings in such models today stem from easier maintenance and smaller building space requirements, lower environmental cost and energy consumption, less noise, and reduced personnel costs to support the systems.

A technology that had started out with wooden half-barrels rocked by muscular assistants had morphed into full-size cockpit interiors that integrate 50 years of actual aeronautic innovations to produce all the variables of altitude, gravity forces, system glitches, and communications of the real things—giving instructors the power to prompt, track, and tweak the learning curve of the new generation of pilots and flight crews. In fact, flight simulators were increasingly used to train aircraft mechanics and maintenance personnel, as well as pilots and aircrew.

The adoption of flight simulators for training has led to further integration of simulators with the design, testing, and construction of new aircraft. In many cases today, pilots train on simulators with new airframe designs even before the first prototypes of aircraft are ready to be test flown. Thus, when new aircraft are ready for introduction, the availability of skilled crews can shorten the fleet activation time. This feedback loop of actual and simulated aircraft performance yields still more cost savings—as well as informing the aircraft manufacturers of potential final-stage alterations in aircraft design and operation and suggesting retrofitting ideas.

Standards and Certifications

In parallel with the technological evolution of flight simulators, the regulatory mechanisms for pilot certification and aviation standards have kept pace. The FAA has incorporated flight simulator training into its rules, guidelines, and enforcement strategies to the point where the vast majority of pilots have trained on simulators.

Aspects of the flight simulator field covered by the NSP include manufacturing processes, approved data standards, ways and means of evaluation, modifications and upgrades to equipment as

well as to usage, enforcement and review flow, and negotiating cross-border agreements.

The NSP encompasses the Simulation Quality Management System (SQMS), which enumerates assessment tools and program requirements that the FAA has identified as key to the NSP mission of continual improvement of flight simulator training and thereby to the constant dedication to its fundamental mission of improving safety in aviation. The SQMS is particularly focused on the “output” of the system, that is, “credible flight crewmember training, evaluation, or meeting flight experience.”

This output is produced in two ways. One is by certifying the personnel engaged in flight simulator training management. The other is by keeping the gains of civil aviation innovation, practice, and research flowing into the flight simulator training field. One mechanism of achieving this second outcome is the designation of simulator evaluation specialists to serve on the Flight Standardization Boards and Flight Operations Evaluation Boards administered by the FAA. This keeps managers of flight simulator programs up to date on changes and trends in aviation safety and helps them devise ways to adopt these trends into their training management regimes.

The FAA through the NSP embraces a very comprehensive approach to simulator use. Programs are organized across a range of disciplines and draw on the widest scope of FAA-responsive fields and competency areas, such as through fixed-wing and helicopter branches; through job descriptions inclusive of flight engineers, flight navigators, aircraft dispatchers, and others; through intensive focus on international civil aviation aircrew training issues; and through integration of knowledge updates from the fields of navigation, communications, surveillance, airspace systems engineering and research, and instrument flight operations procedures and standards.

One factor driving the adoption of flight simulator training is the continuing expansion of the fleet of technologically advanced aircraft (TAA) as opposed to what the aviation industry refers to as legacy aircraft, or those with less aerodynamic design and fewer digital, electronic, electromechanical, or smart-material elements. With each new TAA model introduced, the manufacturers and programmers of flight simulators are compelled to keep pace. Similarly, pilots and pilots in training

must turn to these enhanced simulator stations in order to remain up to date in their skill sets. Operators of flight schools therefore operate in a generally friendly competitive environment in which they seek to maintain competence and contemporary experience levels appropriate to an always-changing profession.

Online Developments

The great allure of flight has over the years attracted millions upon millions of individuals to test their skills, resourcefulness, and imagination. This consistently spreading popularity has in turn convinced the software developers of entertainment and utility programs for the personal computing world to invest substantial quantities of creative resources in the development of such now-familiar programs as Microsoft Flight Simulator. This particular product, initiated as an early personal computer-based video game with its first version introduced in 1982, has helped at least two generations of pilots find their way ultimately into real airborne cockpits.

Microsoft Flight Simulator also spawned many competitors, which in turn helped spur acceleration in the quality, verisimilitude, adaptability, and eventually some components of a certification-level flight simulator experience that can be taken in the comfort of one's home. Indeed, the FAA and its like agencies in other parts of the world now encourage and accept some home flight simulator training hours as part of their certification course requirements.

Alternatives to the Microsoft product line have included FlightGear, an open source, free simulator program known for incorporating some National Aeronautics and Space Administration (NASA) modeling resources and operable on systems including Linux, Mac OS, Windows, and FreeBSD; X-Plane, a simulator program adapted to a range of software platforms and hardware types, including Mac OS, Linux, Windows, and Android; and a wide range of other products of varying degrees of complexity, realism, game play value, and educational value.

With the 1990s advent of the Internet as an increasingly central feature in people's daily lives, the wide adoption of personal computer flight simulators tended to generate online communities of players who reviewed, passed along, modified, and

team-played the various titles, and even created their own.

In turn, this type of home-based activity seems to have meshed well with the hobbyist or enthusiast mentality of much of the private aviation population, giving rise to such organizations as the Virtual Air Traffic Simulation Network (VATSIM). This group, with some 250,000 members claimed worldwide, has earned the respect of many in commercial and even military aviation, and the FAA has on occasion used VATSIM's online flight simulation network capabilities for its own research. VATSIM and other organizations like it, such as Angle of Attack and the AVSIM Community, conduct the bulk of their activities online but do hold a number of well-attended conventions and events where flight simulator technology and technique are explored and many far-ranging topics related to aeronautics, aviation, and computing are analyzed and discussed along with ideas on education, safety, and regulatory issues.

The Installed Base

Student pilots may start their journey to pilot certification on home-based personal computers, but at some point they will graduate to flight simulators operated by flight schools of various physical and business configurations. These schools must meet FAA requirements for instructor and technology certification, as stipulated through the NSP.

Following their initial success, avid fliers will return to the simulator at different stages in their aviation career, visiting different parts of the far-flung installed base of flight simulators. These may be in certified flight simulator stations operated by privately run flight training schools and institutions, in facilities built and run by aviation and aerospace manufacturers or by the various branches and units of the military, or in many cases by the major airlines themselves.

For example, Delta Air Lines, the world's largest commercial carrier, operates a well-refined system of simulator-based courses through its in-house flight simulator stations. These are directed by the Delta Business Programs division's Training and Consulting Services unit. One component is the Delta Aircrew Training Centers in Atlanta, Georgia, and Minneapolis, Minnesota, where pilots are trained to industry standards and tested on recurrent proficiency checks for at least 12 aircraft from

manufacturers Airbus, Boeing, and McDonnell Douglas. Delta professional pilot training staff use more than 30 flight simulators, both fixed base and full motion, in this system.

NASA, too, has its flight simulators and, befitting the world's greatest training organization for astronauts, NASA is said to operate the world's largest single flight simulator. Installed at the Ames Research Center in Mountain View, California, the NASA Vertical Motion Simulator (VMS) is used to "explore, define, and solve issues in both aircraft and spacecraft design," according to the space agency. The VMS is customizable to any aerospace vehicle, "whether existing or in the design stage." At various times and for specific missions, simulated vehicles have included the space shuttle, fighter jets, helicopters, and a blimp.

The VMS incorporates five portable interchangeable cab units and a motion base set within a silo more than 60 feet high and 40 feet wide. Out-the-window graphics, high-fidelity flight controls, and exactly accurate response mechanisms in the VMS are crafted and refined in the Virtual Lab connected with the facility. NASA operates this advanced flight simulator complex in an integrated manner with its separate FutureFlight Central and Crew-Vehicle Systems Research Facility in order for both to provide simultaneous cockpit and air traffic control perspectives and to analyze system-level concepts across multiple operational domains.

In November 2013, the FAA promulgated its final rule, or set of amendments, to the Airline Safety and Federal Aviation Administration Extension Act of 2010. This latest rule set was designed to "ensure enhanced pilot training" both in initial training phases and through remedial training protocols. In its ruling, the FAA explicitly identifies improvements to flight simulator operations and standards as key to the future of pilot training. The act now mandates, for example, that air carriers "use data to track remedial training for pilots with performance deficiencies, such as failing a proficiency check or unsatisfactory performance during flight training."

The act also addresses perceived training gaps needed to deal with conditions such as wind gusts, crosswinds, stalls, upsets, and various runway situations. Many of these performance and training issues have been uncovered through the analysis of data collected in real time during actual flights, thanks to the

online capture of flight data. The new rule announcement by the FAA specifically notes that air carriers will have five years to implement all the changes, as this time is judged necessary for “software updates to be made in flight simulation technology.” While the cost to the industry of implementation is estimated at up to \$354 million, the FAA has projected the benefit at nearly \$700 million.

Airport Administration

Any airport in the United States is part of a transportation network that is characterized by its immense scope and complexity. This complexity exists at several levels: within the airport as a single entity, as part of the aviation network, and as a part of the larger national transportation network. According to the U.S. Federal Aviation Administration (FAA), there were over 19,000 airports in the United States as of 2011. Of these, approximately a quarter are open to the general public. Slightly over 500 airports are classified as commercial service airports that serve a minimum of 2,500 passengers each year.

At airports complexity exists on several levels. There are internal operations and those in coordination with other airports on both the national and international levels (this is particularly true of airports that are part of “hub-and-spoke” networks). There are interactions and coordination required with ground transportation either as means of conveying logistical support to the airport or sending goods to other transportation centers (as is the case with services such as FedEx or UPS).

Further, there are a wide variety of business operations that exist at airports either as part of the required operational infrastructure, air carriers located on site, support for air carriers, or providing goods and services to passengers. Then, there

are aspects of running an airport that are political, economic, social, or environmental in nature. They exist and are distinguished by the geographical location of an airport and its surrounding topography and population centers. Finally, there is the complexity of dealing with governmental and non-governmental organizations at all levels.

Airport Administration Organizations

Airport administration is the means by which an organization oversees, manages, and implements every one of the tasks required to ensure the safe, economical, and effective operation of an airport. The administration organization (sometimes also referred to as the airport operator or management) exercises management and control over the airport. It has complete responsibility for every aspect. It can be either a governmental or a purely commercial organization, although it should be noted that there is currently (2013) only one airport in the United States, at Branson, Missouri, that is managed by a purely commercial entity.

Airports can be managed and operated as individual sites or by organizations that manage several airports (an instance, frequently found where port authorities are the governing body).

Airports are sometimes managed by a metropolitan governmental entity (directly or the authority may be delegated to an organization that reports to the municipality), a county, or directly by the state. The Colorado Springs, Phoenix Sky Harbor, and Salt Lake City airports are owned and operated by the cities where they are located. Rochester, New York, and Cincinnati/Northern Kentucky airports, on the other hand, are managed by counties. Honolulu airport is owned and operated by the state of Hawai'i.

Some airports are managed by autonomous airport or port authorities that conduct all management, administrative, and financial operations. They exercise a great deal of independent management and operations, although they do have regulatory obligations to the federal, and sometimes the state, Department of Transportation. Louisville International and Indianapolis airports are examples of airports run by airport authorities.

Finally, there are airports that are managed by port authorities. In Massachusetts, Logan (Boston) and Worcester airports as well as Hanscom Field are managed by the Massachusetts Port Authority (Massport). Massport, which also manages

the shipping at the Port of Boston, is a state-level agency. Its revenues of approximately \$8 billion annually have ensured that it operates at a profit and for that reason, it can operate without tax-funded appropriations.

Another instance of a port authority managing airports is the Port Authority of New York and New Jersey (PANYNJ). Existing since the early 1920s, the PANYNJ has managed tunnels, bridges, bus terminals, port commerce, rail transit, and airports for the New York City metropolitan area. Currently, it manages five airports: JFK, LaGuardia, Newark (New Jersey), Teeterboro (New Jersey), and Stewart Airport located near Newburgh, New York.

Administration and Regulations

Regardless which type of organization administers and manages the facility, airport administrators must comply with the regulations of both federal and state organizations. On the federal level there is the Federal Aviation Administration (FAA), one of 10 administrations that are part of the U.S. Department of Transportation (DOT). The FAA's stated mission is "to provide the safest, most efficient aerospace system in the world." It is the regulatory agency for all aspects of air travel.

For airport administrators, however, the most critical area of FAA activity is the process by which airports apply for, receive, and work to keep their Airport Operating Certificates. The list of criteria that must be met provides an insight into the types of issues and operating areas that airport administrators must address. Usually, FAA inspections are performed annually, but there can also be unannounced inspections. In any case, the criteria must be constantly kept in mind by airport administrators in order to ensure that every aspect of the site operates as it should. Requirements are disseminated by the FAA in a manner to ensure that administrators are aware of the requirements and can plan and implement maintenance and new initiatives.

Inspections confirm that all FAA administrative paperwork has been kept up to date and is complete. Safety inspections of various sorts are conducted. Among these are inspections of the runways (because of the force of a plane's landing on the runway, cracks and potential buckling are causes for inspection and maintenance). The areas around the runways, particularly where there is wildlife (animal strikes are a cause of concern and

have been the cause of several crashes) or where individuals could inadvertently access the runway are inspected as well. Lights and signs on the runways are also inspected. Because fire is always a possibility at an airport, rescue and fire-fighting drills are conducted and evaluated by federal inspectors. Fueling facilities and night operations are also inspected.

The specific ways in which airport administrators interact with the state aviation authorities varies from state to state depending on what the state legislature has deemed to be appropriate for those state agencies. In most instances, the state's department of transportation aviation section regulates, oversees, funds, or otherwise supports several areas that directly affect the operation and management of airports.

In North Carolina, the state's DOT has an Aviation Division responsible for all aviation functions regarding state system planning, airport and aviation system development. The Aviation Division also provides funding to communities for constructing and improving airports throughout the state. In New Mexico, the DOT's Aviation Division has several objectives. Those objectives of most interest to airport administrators are obtaining financial grants to improve aviation infrastructure, supporting the development and maintenance of airports, and implementing aviation safety initiatives. Airport administrators in Florida work in cooperation with the Aviation and Space Ports Office which is part of the state DOT. This office performs inspections, licenses airports, supports airport development and maintenance, and regulates some construction until that responsibility can be assumed by local authorities. In New Hampshire the Bureau of Aeronautics (part of that state's DOT) has the mission of planning, constructing, and maintaining airport facilities (note this in effect means support and not actually performing the maintenance). Its objectives not only emphasize safety but also ensure that the part aviation plays in that state's tourist industry is promoted.

Airport administrators must also work with municipal governmental organizations, although the nature of that relationship can vary widely. When the local government (town, city, county) is the owner and the operator of the airport, conformance to regulations is quite straightforward. As the owner, the local municipality or county makes the rules for

its own airport, and administrators must ensure that they are followed. When the airport operates under an authority other than the local government, administrators must sometimes negotiate with local authorities or work out how airport operations will be within the regulations of that authority.

Sometimes, local organizations that are not part of any government must also be recognized by airport administrators, and working relationships with such organizations must be established and maintained. These other parties may include civic or environmental groups that voice their concern over issues such as noise pollution.

Administration and Management Operations

Management and administration of an airport, regardless of size, is a complex affair. While the scope and amount of detail and nature of issues can vary, most airport administrators face many of the same issues in ensuring that the airport under their management functions correctly. Some of these issues are obviously difficult. Others may seem to be easily resolved by implementing technology but, without proper planning, they can create even larger problems (such as the 16-month delay of Denver airport's opening because of a malfunctioning baggage handling system). Long-range planning for facilities enhancements, additions, or maintenance to include the all-important financial components is a part of every administrator's job.

There are infrastructure issues that must be managed as well. These include runway design, maintenance, and construction, and lights and other navigation aids. These items are funded by the FAA but their maintenance is the responsibility of the airport. Infrastructure also includes local transportation to and from the airport that has a direct effect on how well the airport serves its passengers. Depending upon the location, this may include roads and commuter rails, such as those found in Atlanta and at Reagan National Airport in Washington. Local transportation system capabilities such as taxis, limousines, and buses are another area of concern for administrators—not only their availability but also how the airport makes that transportation accessible.

The entire physical plant at the airport must be maintained and at times expanded. This includes hangars and other facilities that are made available to

air carriers, as well as parking and buildings used by passengers (terminals and concourses). The activities required to provide a place for amenities for passengers such as services, food and drink, and goods for purchase are also part of the facility operation.

Safety and security and coordination with the Transportation Security Administration (TSA) for checking passengers are other areas of coordination. Local security and safety is the responsibility of the airport administration, regardless whether it is provided by private security, local law enforcement, state police, or, as occurred shortly after the 9/11 attacks, the National Guard. Emergency plans for any safety or security contingency must be created and implemented by the administration.

Airport Gate Assignment Problems

One of the key issues in air travel is assigning gates in an airport to individual aircraft. Finding an optimal solution to this problem is becoming ever more critical as air travel increases and airports become more congested, increasing the pressure to use space efficiently to increase the number of flights

that can be handled at an airport while also preserving a reasonable experience for passengers on those flights. The goal of the Airport Gate Assignment Problem (AGAP) is to optimize gate assignment, taking into account many factors. It is an extremely complex problem, classified in mathematical terms as an NP-hard problem (nondeterministic polynomial-time hard) problem, meaning that there is no known algorithm for optimizing it within a practical amount of time.

The Airport Gate Assignment Problem

The Airport Gate Assignment Problem is concerned with optimizing gate assignment, with particular regard to passengers who must connect from one flight to another in a limited period of time. The basic concept behind AGAP is simple—each plane must be assigned to one gate, and no two planes can be assigned to the same gate at the same time—but in reality the problem is quite complex because of the number of factors involved.

Because most airlines today operate on a hub-and-spoke system, where most flights are to and from one or more hubs, and flying between two nonhub points usually requires flying to a hub, transferring to another plane, and then flying to one's destination, gate assignment is a particularly important aspect of airline management. The problem is complicated by the fact that normally different gates, and perhaps even different terminals, may be used for the arriving and departing flights. While passengers tend to prefer tight connections, in order to spend less total time on their flight (and less time waiting in the airport), booking systems require a specific amount of time between two connecting flights in order to raise the probability that the passenger can actually make the connection; however, if the time allowed is near the minimum, it raises the probability that any delay or disruption will cause the passenger to miss the connection, thus introducing further disruption to the system.

The "turn" is the period of time an airplane is on the ground between arriving and departing flights, and an airplane must be assigned to a gate for every turn. Gate assignment is based on several factors, including the geography of the specific airport (including walking time between gates, and the distance baggage must be transferred between flights), the size of the aircraft, the number of passengers on a flight that must connect with another flight,

and the amount of time they have to make that connection. Gate assignments also play a key role in maintaining flight schedules—one delayed flight can disrupt many other flights due to constraints in the facilities and equipment available—and for this reason “gate rest,” meaning a period of time when a gate is idle between the departure of one flight and the arrival of the next, is included in AGAP models.

Approaches

Initial approaches to AGAP applied quadratic assignment techniques to the AGAP, but these approaches require substantial computing time to arrive at a solution and have difficulty handling uncertain information and multiple performance criteria, both of which are absolutely basic to the real operations of air travel. More recent approaches use knowledge-based approaches to developing heuristics, incorporating expert knowledge and developing a system of rules that can create optimized gate assignments and also make new assignments quickly when required due to changing circumstances or unforeseen events like mechanical failures and weather delays.

For instance, Soi-Hoi Lam and colleagues developed a system, InGates (Intelligent Airport Gate Assignment System), based on analysis of a real-time AGAP. InGates uses an intelligent agent to determine candidate gates for each airplane, using production rules based on factors including the compatibility of particular gates and particular planes, airplane capacity, conflicts between adjacent gates, and transfer distances for passengers and baggage. The goals for an optimal solution include minimizing delays, transfer distances for baggage and passengers, and changes to pre-established assignment, and maximizing use of gate with aerobridge facilities. Results from a test data set from Singapore’s Changi Airport, including over 200 flights in a 24-hour period, found that InGates could assign aircraft to gates in a manner similar to manual assignment methods and could do so quickly while requiring minimal computing time.

Common Use

Many airports were constructed on the exclusive use model, meaning that each airline had its own dedicated space for gates, check-in counters, baggage retrieval, etc. However, more recently the common use model has become popular as a

A gate lounge area at Edinburgh Airport in Scotland in 2009. Because one delayed flight can disrupt many other flights, “gate rest,” or idle time between the departure of one flight and the arrival of the next, must be considered when assigning gates.

means to provide services at lower cost, use airport facilities more efficiently, and provide a better passenger experience. The advantage of the dedicated use model, for the airline, is that they have maximum control over their operations, while for the airport operator, they are guaranteed to be paid for the space whether the airline is using it or not. However, the dedicated use model is less flexible, because often space dedicated to one airline is not used, while other airlines may not have sufficient space to meet demand for their services.

The common use model, which is still less common in the United States than in some other countries, actually represents a continuum of choices, from exclusive use (the most restrictive), through mixed use, preferential use, and common use (the least restrictive). In the full common use model, assignments for gates and other facilities are made

without any preference to the particular airlines but with the goal of maximizing efficient operation.

While common use introduces flexibility, it also increases the complexity of the problem, because more flights and gates must be considered all at once, as opposed to each airline managing just its own planes and gates. This places a great burden on the airport operator, who must not only make the assignments but also monitor conditions within the airport and adjust assignment if necessary (for example, if flights are delayed or cancelled). Some argue that this is in fact an additional advantage of common use systems—by taking responsibility for gate assignment and facilities management away from airline operators, they are free to concentrate on providing air transportation, which is their specialty.

Airport Hubs

Airports are often classified, planned, and operated as part of a hub-and-spoke system of air routes, as opposed to a point-to-point model. The functionality of hub-and-spoke is largely based on the fact that travelers change planes at the hub airport in order to reach their final destination at another airport at the end of one of the spokes. The same principle applies to the operation of cargo air traffic.

Varying Definitions and Terms

The Federal Aviation Administration (FAA) in its National Plan of Integrated Airport Systems (NPIAS) defines the hub classification of an airport as either large, medium, small, or non. These classifications are based solely on the number of enplaned passengers who use the airport on an annual basis. Across the airline industry, however, the term *hub* is used more generally and refers to any airport where most of an airline's passengers use the airport to transfer between flights in order to reach their destinations.

Other terms in use by specific airlines or by airport industry officials include "key city" and "focus city," although these sometimes refer to somewhat different situations. Focus city originally specified a destination airport rather than one where connecting flights were assembled; however, the term's use by various carriers to promote certain flights has led to its more general adoption to refer to either a destination or transfer airport that an airline uses on a fairly heavy basis. In a related manner, key city is loosely defined but usually refers to a smaller hub airport that an airline nevertheless uses somewhat heavily and seeks to promote as both a transfer point and a destination.

Some hubs are strongly identified with major carriers and even serve as headquarters for a given airline. For instance, Delta Air Lines with its headquarters in Atlanta, Georgia, has a major fleet and gate position at Hartsfield-Jackson Atlanta International Airport—while also maintaining a large presence at 10 other hubs in the United States, Japan, and France. United Airlines utilizes 10 hubs, all of them international: eight in the continental United States, one in Guam, and one at Narita International Airport in Japan. United's corporate headquarters in Chicago is connected to its large gate complement at O'Hare International Airport.

In a similar vein, the corporate headquarters of Southwest Airlines is at Dallas Love Field, one of 15 airports that Southwest calls its focus cities. JetBlue uses the term *focus city* for the six major and minor hub airports it utilizes and the term *key city* for a range of other destinations.

Key city pairs are an allied concept in airline and airport planning and operations; such a pair may include one or two major hubs. American Airlines, for example, has a business model built around several key city pairs, with JFK New York–London Heathrow the predominant one. Both of these airports are major hubs, serving large international business passenger populations, with origin and final destination points often elsewhere in their host country or in other countries altogether. American Airlines’ partner British Airways, for instance, carries more than 4,000 first class or business class passengers daily between Heathrow and international destinations.

When a hub is used mainly for transfer activity for international travelers, it may be referred to as a transcontinental or “transcon” hub. When the passengers mainly are traveling within a country, however, it will be known as a regional hub.

Savings and Costs

It behooves bodies such as municipal planning organizations to understand the hub and network strategies of airlines when setting out to attract them to their localities. The ability to assemble robust passenger volume is one aspect; another is fuel usage. Airlines and regulating bodies alike are interested in the use of hubs as energy-conserving and cost-controlling solutions. The FAA has sponsored or conducted a wide range of studies to identify performance metrics of air carriers using key city pairs and related hub infrastructure. In its Modernization and Reform Act of 2012 (a part of its “Next-Gen Performance” program), the FAA mandated the tracking of such data as fuel consumption based on average distance flown between key city pairs, a component of the hub system.

The FAA uses its funding capacity as an incentive for municipal and regional planning authorities to make service-area airport decisions with energy conservation and related matters as part of the criteria. By emphasizing the cost-savings aspects as well as the potential pollution-reduction aspects of the hub-and-spoke system, the FAA in this manner

Delta aircraft cluster around Concourse C at Hartsfield-Jackson Atlanta International Airport in Atlanta, Georgia, in April 2012. The airport is a major hub for Delta Air Lines.

adds a practical environmental metric to the market-based calculations that typically drive such decision making.

However, some industry analysts point to growing congestion and delays at hub airports in order to advocate for a pendulum swing back to more point-to-point air travel. These observers point to inefficiencies in time management and failed promise in fuel savings due to overuse of hubs; in other words, the system may have reached the point where it is a victim of its own success. Fuel burned during long taxi and runway delays does indeed undermine the inherent fuel savings of a hub airport operations goal. Many of these analysts, however, see a need to blend the two systems, rather than make an either-or choice between point-to-point and hub-and-spoke.

Among the key drivers of when and where to apply either model will be the availability of appropriately sized aircraft (appropriate to passenger volume and airport fleet capacity), the economic underpinning to support direct flights, and the

continuing evolution of collaborative decision making (CDM) measures among airport administrators and partners, which can support enhanced hub operations even under the pressures of over-capacity demand.

facilities, and any variation is primarily based on configuration of terminals and layout in relation to areas used by airplanes. These include runways, taxiways, and aprons. Additional variation outside the terminal is based on what airport management have decided to do with excess real estate.

Traditionally, airports have made money through fuel sales to airlines, renting hangars to commercial enterprises and private interests, and fulfilling government contracts. In recent years, airports have attempted to widen their profit margins through real estate development. Many of these ventures have included unconventional uses for previously underutilized land. In terms of public relations, the primary task of airport management is to bring positive attention to the airport itself, as opposed to letting the airlines draw all the attention. These efforts usually focus on making airport officials appear like "real" people and making the facility both as personable and pleasant as possible.

The Parts

In the most intuitive terms, the operations of any given airport can be separated into inside operations and outside operations. On the outside of the airport, there are three types of vehicle ways. Aprons are the areas where aircraft park. These areas are also sometimes called ramps, and they typically hold from five to 10 planes. Taxiways are the paths planes use to move from aprons to runways and vice versa. Runways are the paths from which aircraft take off and on which they land. Tasks regarding ground control, traffic patterns, air traffic control, and auxiliary issues must be constantly maintained for proper and safe operation. The air traffic control tower serves to monitor the activity of approaching and departing aircraft as well as make weather observations and collect other data. From that position, ground control staff monitor the activity of aircraft taking off from or landing on runways, as well as those on their way either to take off or to hangars via taxiways.

Traffic patterns on runways, taxiways, and aprons are dictated by various navigational aids and markings. To differentiate between the two major types of vehicle paths, runways are painted with white markings, while taxiways are painted with yellow markings. To assist incoming planes in the dark or in poor weather conditions, runways and taxiways are also marked with color-coded lights;

Airport Operations and Marketing

While many of us do not think outside our own affairs when having to navigate the gauntlet that is an airport, there may be more to airports than you think. They not only employ a great number of people but also host numerous corporate and governmental entities. Within the terminal walls, airports host small commerce ventures (including restaurants and shops), an array of advertisements, and strategically placed security checkpoints. Outside the terminals, there is less variation between

these lights indicate not only the type of strip but also the length of the remaining field. Finally, there are a number of signs that convey important messages to pilots. These signs are as varied as traffic signs on a highway and are just as essential.

There are also a number of auxiliary staff in the ground crew who are critical to the operation of the airport. Ground crew operate fuel trucks for airplanes, service vehicles that perform minor repairs and maintenance, and tugs that help move planes into position between flights. Aircraft rescue and fire-fighting vehicles are always available. For all intents and purposes, these vehicles are identical to their nonairport counterparts. As with the inside of the airport, security personnel are needed to detect and prevent dangerous incidents. Finally, lawn care and other grounds maintenance crews are needed to keep up the outside appearance of the facility.

Inside the terminal, small commerce ventures, art displays and advertisements, security stations, lounges, and other passenger services are key to operations. These activities may take place within multiple terminals or in a single large terminal within one facility. Many airports are broken into several satellite terminals; these buildings are detached from other airport buildings. This is done to allow for the maximum number of plane slots by utilizing all potential area outside the terminal. Another way of utilizing maximum exterior area is through semicircular terminals. This design allows for more planes and decreased travel time within the terminal for passengers on foot.

Small commercial facilities are certainly a critical aspect of airport terminals. These serve many purposes, not the least of which is to distract waiting passengers. These ventures commonly include franchise shops and restaurants, duty free shops, hotel kiosks, and car rental agencies. The interiors of terminals are most often decorated with art displays and advertisements, the majority of which represent revenue drawn for the use of valuable advertising space.

Security teams within airport terminals are equipped to deal with events ranging from mundane passenger disruptions to serious terrorist events. Passenger services are also available; these include but are not limited to providing information to those who need it and transportation for those with special needs. Many airports are also equipped with a range of lounges; these include

those for VIPs (determined in a variety of ways), smoking areas, and simple areas that provide wireless Internet and device-charging stations.

How Airports Make Money

In recent years airports have become less profitable than they were in previous decades. Construction costs have increased. Government loans and grants have decreased, and economic downturns have allowed fewer people to travel by air. Traditionally, revenue sources for airports have included fuel sales, agricultural leases, ramp fees, and government grants. While fuel sales and hangar leases have been highly profitable in the past, they may not be the major profit source for airports in the future. There are many within the aviation industry who put heavy emphasis on the development of real estate assets.

The future of real estate development will likely occur through investment and enhanced property management. It is thought that real estate development and enhancement will provide long-term revenue, but this revenue will not necessarily be airline related. To this point, this has most typically taken the form of leasing to franchises and other interested businesses who seek to have a presence inside the terminal.

There have also been other options for using airport real estate for profit that are more unconventional. Georgia's Hartsfield-Jackson Atlanta International Airport hosts that state's largest blueberry farm on its grounds. San Francisco International Airport and Long Beach Airport both take advantage of solar technology to cover electric costs. Similarly, Boston's Logan International Airport has used wind turbines to offset energy costs and take advantage of environmentally friendly government grants as well as the associated good public relations (PR).

Airport Public Relations

As owners of profit-oriented businesses, the management of airports must put significant efforts into public relations. Marketing experts, including Seth Godin, have identified many ways through which airports can improve their public image. These include but are not limited to tactics that incorporate social media and other elements of Internet culture. The bulk of these solutions can be lumped into improvements in management issues and passenger treatment.

The Internet culture that has developed in the last two decades has made people more connected than they ever have before. Unfortunately, many established public players have been slow to adopt said culture, and airport chief executive officers (CEOs) have often been included among those who have ignored the potential of Internet culture, for both good and bad. In fact, some airports are so late into the game that many facilities have had to compete for their own names on Web sites, Twitter handles, etc. This can range from being inconvenient to damaging, depending on the nature of the individual who claimed the name first. Much of Internet culture challenges hierarchical business models and can be highly unpredictable. For example, social media can be dangerous to the public image of an airport. It used to be that only representatives of large corporations or public figures could be detrimental to the public image of an airport. In this age of social media, one person's bad experience can be disastrous to the public image of an airport, and news of it can spread worldwide in hours. Additionally, the Internet provides nonconventional options to travelers that provide dangerous competition to airports. Through Internet channels, travelers are now able to find nonair travel options, including buses, carpooling, trains, and combinations of travel options, that they may have not been able to find in previous eras.

In addition to being better able to find information about airports and other travel options, potential customers are also highly fragmented in terms of media consumption. In previous eras, it was possible to reach entire demographics or even populations through one or two media outlets. In times past, these were network television or the one or two newspapers that typically dominated metropolitan areas. In contemporary America, people may not only be watching one of a hundred cable channels, they may also be getting their news or entertainment from any number of Internet sources. Furthermore, customers are highly fluid in their preferred modes of entertainment. What is popular today might not be tomorrow. Thus, even if marketers are able to figure out what media their targeted demographic is consuming, this could change in a short period of time.

As far as management issues go, administrators of airports, and the entire air travel experience, have been criticized as being overly sterile, without

joy, and just plain no fun. Critics argue that the current air travel system is riddled with elements that fill travelers with anxiety, and measures must be taken to remove stressful elements from that system. Many of these factors center on the emphasis placed on filling every seat of every plane on every flight. While filling seats may be key in maximizing fuel utilization, the experience of air travelers could be improved if less stress were placed on putting people in seats.

Additionally, the managers of airports, and the airports themselves, need to be more personable. PR experts contend that many of our contemporary airports are completely without character. Critics have also claimed that airports and their management are completely without accountability. When mistakes are made in airports, responsibility is passed from airlines to flight crews to passengers, etc. Regardless of the actual cause of the problem, the management of the facility are often perceived as being to blame for unfortunate incidents. Thus, when airport management takes more responsibility for these problems, they appear to possess greater integrity.

Much can be done to improve the perceived image of airport management by treating passengers better. By extending personalized service to passengers, the experience is humanized and perceptions will improve. A prime area for improvement in this regard is customer service; if customers' problems are addressed in a polite and caring manner, they will not only be less likely to report negative experiences to potential future passengers but also may actually report positive experiences. Finally, and potentially of greatest impact, if airports offered higher quality food selections for more affordable prices, great strides could be made in public relations. That is not to say that airports should eliminate their fast food options or high-end dining for those who wish to have these experiences. However, when people are tired and stressed from travel, many middle-class passengers want an affordable meal of higher quality than fast food.

Airport Parking and Ground Transportation

At airports the American aviation system intersects with other modes of transportation, including automobiles, buses, and trains. Airports are places where federal responsibility for managing and regulating air traffic operations coincides with state and local governments that own and operate most airports. Authorized in 2003 as part of the Vision 100—Century of Aviation Reauthorization Act of the Federal Aviation Administration (FAA), the Airport Cooperative Research Program (ACRP) helps the airline industry to develop innovative solutions to efficiently plan airport operations, including airport parking and ground transportation.

According to the ACRP, operators of airport parking facilities focus on customer service more than do publicly owned facilities. Airports present a passenger's first or last impression of a community, and airport parking facilities present first or last impression of the local airport. Airport operators work to give customers a higher level of service than

other public parking facilities, so airports often are the first to implement innovative parking services and technologies.

The FAA requires that commercial-service airports be as financially self-sustaining as possible. To meet this requirement, airport operators rely on revenues from airlines, including landing fees, terminal rents, and other charges. They also depend on concessionaries and other tenants, such as rental car companies, ground transportation providers, and public parking facilities.

Airport managers frequently compare their own airports with other airports of similar size. Size is defined in terms of the number of annual originating and destination airline passengers, as they are the customers who use parking facilities. Most medium- or small-hub airports serve few connecting passengers, so comparable airports can be identified using the number of enplaned or deplaned passengers. Many large-hub airports serve as hubs for a major airline, garnering them a large number of connecting passengers.

Public Parking Revenues

Commercial service airports usually provide over 1,000 parking spaces and several large-hub airports provide over 15,000 public spaces. These large parking facilities are necessary because over 70 percent of all passengers travel in private vehicles and some of them park at the airport for several days. Public parking is usually the single largest revenue source at airports in the United States, providing approximately 25 percent of all airport revenues and more than 40 percent of nonairline revenues. Annual parking revenues often total over \$10 million at small-hub airports and over \$100 million at the largest airports.

Surplus revenues from public parking often provide funds to support other airport operations that make no income or require subsidies. Surplus parking revenues also represent the single largest source of debt-free cash flow to fund airport capital improvements. Parking revenues are shared with the airlines at some airports, which helps maintain existing service and attract new airline service.

Airport managers frequently cite three airport parking goals. They aspire to provide a high level of customer service for the traveling public and employees. They strive to improve operational efficiency by reducing the costs of parking operations

A Skylink automated people mover station at Dallas/Fort Worth International Airport in Texas. Only about 2 to 5 percent of U.S. air travelers take rail transport to and from airports, compared to 20 to 30 percent at many European and Asian airports.

while maintaining or improving customer service and safety, and they work to enhance revenues and net parking revenues while achieving their other goals. Some airport operators forgo possible revenues to provide improved customer service by providing a high proportion of close, covered parking spaces. Other airport operators choose to defer construction of structured parking and expand surface surfaces within walking distances of the terminal instead.

Baselining and Benchmarking

Airport owners need to develop a baseline to compare parking metrics. The airport operator can collect and analyze “before” data by selecting a

time period to analyze existing data or to collect new data. Progress can be gauged by measuring improvements over a fixed time period. Progress can also be measured by evaluating performance compared to a future target. Some of the more commonly used parking-related metrics to monitor and track parking revenues are facility utilization, customer service, operations, and other aspects of public parking.

In the field of airport parking, benchmarking is the operation of comparing the fees, space numbers, types of products and services, revenues, operational practices, and other areas of an airport’s parking operations with those at other airports. Benchmarking helps airport operators determine how their parking operations rank or compare to such specific measures as parking rates or spaces. Benchmarking can also be used to increase management’s awareness of the operations and facilities at other airports.

The Seven Planning Steps

The Intermodal Surface Transportation Efficiency Act of 1991 (ISTEA) establishes guidelines for airport ground transportation, and the Research and Innovative Technology Administration (RITA) of the U.S. Department of Transportation explains seven steps in a government document called *Airport Ground Access Planning Guide*.

The first step is defining the problem and pinpointing the policy issues that the airport faces, because its unique characteristics and setting define its performance standards. For example, an airport in an air quality nonattainment area must lower its total vehicle miles of travel with airport access to reduce vehicle emissions.

The second step is fully understanding the policy issues and establishing performance measures to use in the monitoring and evaluation program. Airport ground transportation planning issues include quality of traffic flow on the access roads near and on the airport. The number of choices the passenger has between taxi, shared ride van, scheduled bus, limousine, or rail service to reach his/her ultimate destination is important. It is equally important to determine the percentage of the region served by shared ride services, the percent of passengers arriving by other than private vehicle or single ride taxi, and the percentage of passengers arriving in a vehicle with low emissions propulsion.

The third step is collecting the data that documents access conditions and level of performance. Airport access patterns can be understood by examining multiple data sources, including periodic ground access surveys, ridership and revenue data, and time, cost capacity, and usage. The Port Authority of New York and New Jersey has monitored ground access patterns to JFK, LaGuardia, and Newark airports for several decades and has collected valuable data.

The fourth step is understanding existing and future conditions and system performance. San Francisco International Airport is doing pioneer work modeling existing conditions and patterns in ground access, experimenting with parking prices, and evaluating policies for managing and regulating shared ride van operators.

Developing and evaluating statewide and local strategies and actions that improve the intermodal efficiency for the movement of people and goods is the fifth step. Options considered should include a full range of possible solutions beyond highway and rail transportation back and forth to airports. In San Francisco, the private sector developed an extensive shared ride van system with water transportation being discussed. Water transportation services are part of the overall strategies in Boston and New York.

Assessing the effectiveness of alternative strategies and actions and selecting cost-effective actions is the sixth step. The evaluation of alternative strategies can extend beyond analysis of vehicle flows and include such concepts as people and goods mobility, and accessibility to various activities and land uses. In Salt Lake City, analysis alternatives focused on dealing with a serious air quality, non-attainment situation.

The seventh step is implementing feedback using the established performance measures. Strategies implemented are case based. Salt Lake City had an air quality issue and selected a strategy that addressed the levels of pollution from shuttle vans, instead of reducing travel time. Salt Lake City and Washington National Airports provide space for everyone on airport rental car operations in a garage near the terminal. The Massachusetts Port Authority has monitored the air quality implications of its actions, ranging from parking pricing policies to the monthly variations in ridership on its express bus services. The Port Authority conducts

comprehensive ground access surveys every five years to track changes in travel behavior.

Future Planning

With cars, taxis, shuttles, and limousines crowding their roads, a growing number of airports are building or are planning to build a rail link connecting passengers from the terminals to regional metro-rail systems. Europe and Asia have long had airport rail links. In many European and Asian airports, 20 percent to 30 percent of travelers go to and from the airport using rail, but ridership in the United States typically ranges from 2 percent to 5 percent.

Just a few of the largest U.S. airports have rail service dropping passengers within walking distance of the terminals. Airports with rail connections include Atlanta, Chicago O'Hare, New York John F. Kennedy (JFK), San Francisco, Newark, Minneapolis, Boston, Philadelphia, Washington, D.C., and in December 2012, service was extended to the edge of the Dallas/Fort Worth International Airport.

Airports and airport managers are learning that building more parking lots and enlarging roadways are planning practices from the past and that airports of the future will have to embrace the green movement by budgeting more money for programs that reduce their carbon footprint. More federal funding sources for airport rail are impacting airport ground transportation planning.

Airports wanting to build a rail connection can add to existing systems. Seattle's Sound Transit initiative passed in the late 1990s to build a regional light rail system. A 16-mile line, the Central Link, runs between downtown Seattle and Sea-Tac Airport. Oakland Airport is constructing a link to the nearby BART system.

In Salt Lake City, Utah, the Airport TRAX Line is a six-mile rail line extending the existing TRAX system from Arena Station to the Salt Lake City International airport.

Airports and airport planners are considering People-Mover Rail as another design of the future. Some airports have a nearby metro station just out of walking distance, and to close the gap they are building automated people-mover trains. People-movers typically run within airport grounds, so airport authorities can tap funding sources available only for airport projects. Phoenix Sky Harbor International Airport used passenger facility charges to partially

fund its Sky Train, a people-mover that connects to a nearby light rail station. One airport station contains an enclosed moving walkway that takes travelers directly to the terminals. Phoenix Sky Harbor convinced the Federal Aviation Administration to allow it to use the passenger facility charge, a fee added to air tickets, to partially fund its rail project. The Miami International Airport Mover can transport more than 3,000 passengers an hour directly between the airport and the Rental Car Center's customer service lobby. Passengers simply leave their concourse, take elevators to the third-level moving walkway, and are quickly connected to the MIA Mover.

The MIA Mover replaces the Rental Car Center shuttle bus service, eliminating about 1,400 shuttle bus trips a day, and reduces carbon emissions from the airport's roadways by 30 percent.

Airport Passenger Terminals

The first facilities that can be considered airport terminals were built in the early 1920s for the use of airmail. These facilities are now used for the efficient transport of goods and passengers between communities, but they are also an economic engine for the region as they generate employment and are a source of revenue. Airport passenger terminals are one of the principal elements of infrastructure cost at the airport. Several terminals that are architectural masterpieces have not been able to perform the expected functions. Three main basic functions can be attributed to terminals: change of mode (air-land), processing, and change of movement type (holding spaces-movement).

While most terminals are utilitarian in design, some stand out, either because of their architecture or the variety of additional services offered, and are valued for their aesthetic and social function. Several terminals are considered architectural masterpieces such as the the King Abdulaziz International Airport in Jeddah, Saudi Arabia; the Beijing Capital International Airport in China; South Korea's Incheon, International Airport; Lyon-Saint Exupéry Airport in Lyon, France; or Spain's Madrid-Barajas Airport.

An early example of notable terminal design was the Pan Am Worldport at JFK International in New York, opened in 1960 and rebranded as the Worldport in 1971. Used as the terminal for Pan American World Airways, the Worldport was designed by the architectural firm Ives, Turano, and Gardner, with Walther Prokosh of Tippetts-Abbett-McCarthy-Stratton, and included an enormous "flying saucer" roof, the edges of which extended far beyond the terminal's outermost columns. The design of the terminal advertised the modernity of Pan Am, and indeed of air travel itself, tying in to Pan Am's jet age/space age brand identity.

The general trend of airport terminal design since the 1970s has been to tailor them specifically

to their location, both in terms of local transportation needs and aesthetic choices. The exterior of Denver International Airport's Jeppesen Terminal, for instance, was designed by Fentress Bradburn Architects with a Teflon-coated fiberglass roof that resembles the snow-covered peaks of the Rocky Mountains. Inside, the terminal (opened in 1995) hosts both permanent and temporary art exhibits, including Luis Jiminez's sculpture *Mustang*. The terminal is connected to Concourse A by a pedestrian bridge that allows travelers to watch planes taxi below them, along with a view of the Rocky Mountains. Similarly, in Morocco, the Marrakech-Menara International Airport's two passenger terminals combine elements of both modern and traditional Islamic architecture, with the heavy use of glass and marble in the interior evoking memories of much older buildings. In China, Beijing Capital Airport's Terminal 3 (opened in 2008 in time for the Olympics) was designed by Norman Foster, an architect who is also a recreational pilot. The terminal's design is intended to evoke the experience of flight: it is vast (2 miles long), with a roof that rises upward as though floating, and angled cuts in the canopy that result in sunlight shining through. The arrival area of the terminal was designed with input from a Feng Shui expert.

Passenger terminals are the first point of contact for the arriving passenger. Airports are usually subsidized by public entity, so their terminals are highly influenced by political and economic developments. They are important elements of the air transport system as interchange nodes between land and air transport systems.

Passenger terminals play an important role as social connectors and economic engine. Their main characteristics and design depend on factors such as the expected number of passengers and the kind of routes being offered. However, there are social aspects influencing terminals, and the type of passengers is one of them. Many passengers are not interested in extra services if they represent an additional cost. For instance, waiting areas for low-cost airlines can be less comfortable and smaller when compared to the ones provided for the usual passengers. Moreover, terminals have to conciliate the needs of transfer passengers, who need fast and easy-to-find connections, as well as arriving passengers, who are interested in easy connections with land transport, airlines, ground-handling, and retail.

A vast passenger terminal at Bangkok's Suvarnabhumi International Airport in 2007. Such terminals facilitate three main functions: change of mode, processing, and change of movement type, as well as other social functions.

Terminals are usually managed by a combination of public and private management, which creates a unique political role. There are important differences in national attitudes and values that influence local decisions regarding terminals. Important national considerations should be taken into account and consequently will determine the terminal's planning. For most passengers, flying can be stressful, so terminals should ideally be a place to relax and spend time. Shops represent the most common solution for spending time, and some terminals are very similar to shopping malls. For example, in Zurich, the terminal provides such a variety of shops that local residents go there just for shopping.

This transformation of the terminal into more than a connection node between air and land is a result of social changes through time. Nowadays, terminal users look for additional services, such as casinos, cinemas, fitness centers, and play areas for children. Terminals are changing airports, which are gradually becoming small cities in their own right with a great variety of facilities and services, such as in Dallas/Forth Worth in the United States. Moreover, a terminal that provides good facilities for passengers, such

as retail stores and business conference rooms, can generate substantial revenues. Passengers' airport choice depends on the services available, so in general, more services mean more passengers.

The added value generated by an airport can also be perceived in local real estate values, which increase with a relative proximity to this facility. However, being too close to the airport can produce the opposite effect because of the noise.

A terminal's configuration is influenced by the urban characteristics of its surroundings: combined passenger buildings for several airlines are common in smaller communities, and separate buildings are usual in larger metropolitan areas. This might seem a contradiction since larger urban areas have less available space, but these areas need to serve more passengers. Four types of configuration can be found: finger piers, satellites, midfield, and linear.

Nevertheless, terminals are also highly influenced by policy. Security, land planning, and environmental policies are perhaps the most significant. Concerning environmental policies, Frankfurt Airport Terminal 2 uses rainwater for air conditioning and lavatories. Urban planning policies are important to assure the correct integration of the airport with the city and to minimize the impact on the landscape. In Bristol in the United Kingdom, the terminal height was limited to one level on the airside to minimize its impact on the landscape. Moreover, terminals have to be part of a city. As such, there should be reliable land transport to assure its access to everyone.

Regarding security, policy directives often emerge as a form of protection against terrorist attacks. On December 23, 1988, a bomb explosion on B747 Pan Am Flight 103 over Lockerbie, Scotland, resulted in changes to passenger terminals to physically separate arriving from departing passengers as well as the installation of explosives detection equipment. As a result of the 9/11 attack, for instance, only passengers with valid boarding passes are allowed beyond security points.

Despite looking like typical transport infrastructure, passenger terminals are more complex. They generate important social and economic benefits for the community. Moreover, their functions and configuration are more sensitive to social aspects and policy than other transport facilities.

Airport Planning

Airport planning is a multidisciplinary field that encompasses rural, urban, local, and regional land use policies; business development and tax issues; environmental, safety, and national security factors; public and private transportation processes; construction engineering contracting and negotiations; labor relations and regulations; comprehension of federal airspace and aviation rules and practices; and advances and challenges in technology.

The decisions made in airport planning frequently impact the local and regional physical environment and the business and community infrastructure, and they can affect local and regional economies by either stimulating or obstructing related forms of development.

Capacity and Systems

Airport planning typically begins with studies of local and regional capacity projections that cover cargo and passenger volume as well as overarching economic trends and land development issues in a given region. Attention must also be given from the earliest planning stages to funding requirements and sources, as these involve often lengthy hearings, negotiations, and legislation at local, state, regional, national, and sometimes international levels.

Airport planning includes not only the design and specification of new airport facilities but also the structure and function of the airport administration

and operations staffs, facilities, technology, and their associated rules and regulations.

Ultimately, airport planning must take into consideration the National Airspace System (NAS) and the National Plan of Integrated Airport Systems (NPIAS), which were developed by the Federal Aviation Administration (FAA) to standardize and rationalize the infrastructure of air travel and transport in the United States. Some 3,400 airports across the country are categorized by the NPIAS as either (1) primary airports, (2) commercial service airports, (3) general aviation airports, or (4) reliever airports. The standards that apply to each of these categories must be considered during the airport planning process.

In addition to aircraft handling, as well as airline passenger and air cargo support, the planning process for an airport also must analyze the surface transportation links, access, and intermodal structure as part of a comprehensive consideration of all challenges and potential of the airport and its surrounding area.

Congestion and Coordination

The prevailing projections for increasing congestion in air traffic mean that airport planners are well advised to cooperate and coordinate to increasing degrees on a regional basis. In the United States, for example, the regional airport systems planning (RASP) concept is the approach developed and favored by the FAA Office of Airports. The FAA in the first decade of the 21st century made available some \$20 million in planning funds to encourage better regional planning practices by nine of the 10 most capacity-constrained metropolitan airports, as defined by projections to 2025.

The issue of air traffic congestion and a regional approach to solutions is not universally accepted, however. This is due in part to the fact that airport authorities sometimes have different priorities from those of federal, state, or local governments and to the fact that the FAA is mandated to make funding decisions on the basis of national security, which often is not a primary concern in the capital investment decisions of airports themselves. Some major airports, for instance, may elect in their planning to not divert traffic to alternate regional airports as a matter of strategic business and financial policy. This can undermine application of the RASP approach in a given region.

It is largely during the lobbying campaigns conducted by airport developers and their associated elected officials for federal transportation funding that the RASP priorities can be emphasized. However, the issue is further complicated by the fact that more than three-quarters of the metropolitan planning organizations in the United States lack the mandated authority to conduct aviation planning on a regional basis. Many such planning bodies are not engaged in regional revenue-sharing models that would specifically provide motivation for the necessary changes in mandates.

Flexible or Dynamic Approach

In contemporary airport planning, much emphasis is given to flexibility in the design of airfield layout and operational systems, with more planners favoring a dynamic approach that maximizes the ability of administrators to adapt and alter future designs and build-out in response to changing economic, physical, social, and technological parameters. A focus on integrating the airport design and operations into the evolving plans of its commercial, private, and public-sector clients is also of increasing importance. Many of these factors can be studied via computer-aided simulations, and the results can be applied as the planning proceeds.

As with planning in related fields—business, military, institutional—there are valid reasons to approach airport planning with a “Plan B” always at hand. Future economic growth patterns, regional competitive issues in a largely deregulated industry, changing levels of local political support or conflict, new or newly enforced legal mandates, and other unpredictable and uncontrollable external forces can all turn primary planning on its head. These unforeseen developments each come with their own costs, which can drastically undermine what were otherwise intelligently devised budgets and plans.

Operational costs change over time, and the sustainability of these costs must be considered based on service-demand levels and the airport’s desired minimum standards of service.

Delivery of desired service levels over time calls for sharply defined understanding of the local and regional dynamics of any airport. While air passenger volume is projected to double over a 20- to 25-year period (as it has in the most recent such periods), this traffic measure is a global one. Even

while this type of projection has mostly remained accurate as a rough estimate in the United States, for example, there exist many variations across the country. Markets elsewhere in the world have shown even greater variation, for example, between airports sited close to the fastest growing cities in Asian countries such as China and India, and other more stagnant-growth cities within the same countries.

The uneven distribution of passenger volume and the difficulty in predicting local and regional economic shifts as much as two or three decades into the future, puts a high value on the ability to shift build-out and systems integration while maintaining standards and controlling costs as planning proceeds. Airport planning as a discipline now has an engrained “doubling” approach that must be tempered with the reality of changes in economic, environmental, and related social and political pressures that can either spur or hinder expected expansion or can alter priorities due to new local and regional transportation developments such as rail, bus, telecommuting, and other alternatives to air transport.

Fortunately, there is a wealth of software simulation products that can help planners maintain flexibility as they work to project airport expansion and to account for repair, upgrades, and maintenance during variously assumed periods of rapid, flat, or negative growth.

Additional consideration must be given to the expected changes in aircraft activity level, composed of both aircraft operations (takeoffs, landings, touch-and-go) and based aircraft (general aviation “resident” vehicles, as opposed to major carrier aircraft). In some cases, airport planners must incorporate a majority-in-interest approach to aspects of their plans. This means that those air carriers providing the majority of traffic at the airport—and who will be the most affected by rate and fee increases—must be given advise and consent rights to review plans for significant capital investments that are likely to add upward pressure on the airport’s long-term and operational cost structure.

Infrastructure Parameters

At the most basic level, airport planning must account for both the airside or airfield domain as well as the landside or terminal building and

ground transport domain. Airside factors such as runway lengths and orientation, apron and taxiway layout and navigation aids, pushback maneuver space and related aircraft handling arrangements, roadway and building obstruction clearances, jet-blast and noise mitigation, and the alignment of cargo facilities, passenger terminals, redundant safety and fire suppression equipment, and security and maintenance buildings will all be taken into consideration. Integration of all ground service and support service vehicles must be designed into this layout, along with accommodation for various sizes and configurations of commercial fleets and private aircraft. Air traffic control in particular is a section of the airside planning that must be designed and conducted to meet the certification requirements for commercial air service operations standards.

Working with the range of ancillary service providers—food vendors, retail and financial outlets, telecommunications, ground transport rental firms, and the hospitality sector, as well as medical support and security staffs—is part of the people-centered planning process of landside operations. Designing airports to accommodate disabled and special-needs individuals and their health aids, family, and helpers is an essential part of this matrix. Retrofitting existing airports and designing new airports to comply with enhanced national security mandates adds still another layer of planning that particularly affects the landside.

Duty cycles, repair and maintenance schedules, and replacement timetables for pavement and other structural and building components are essentials of planning, as are fuel costs, climate-change dynamics as they apply to population movement trends, and related air carrier issues. These entail factoring in requirements for personnel, materials, supplies and supplier negotiations, and technology upgrades and the associated training needs. Each factor comes with an associated capital investment or operational expense vector.

Administrative staffing and development costs are layered over all of these needs, both airside and landside, and must be continually adjusted to reflect any alterations in plan fundamentals of demand and service level. Only when developed together in a comprehensive model through the use of reliable and contemporary simulation systems can an airport plan be considered capable of producing a

realistic set of assumptions and a coordinated set of budgets tailored to those assumptions.

Environmental Factors

Another vital component of airport planning—and one that has consistently become more pronounced in terms of potential impacts to the structure and cost of layout, operations, and administration—is the environmental component. This category includes such major factors as air, soil, and water quality and protection; wildlife and endangered species considerations; and noise pollution and mitigation. Each of these factors is subject to a range of confirmed, established code and enforcement precedent; each can also be subject to a variety of unpredictable legal challenges of a civil nature, as local and regional constituents learn about developing airport plans and respond with questions about or challenges to the planners' assumptions regarding such impacts.

Beyond such immediate impacts as soil compaction, ground cover disruption, threats to water quality, and air pollution, local and regional stakeholders in many cases are increasingly likely to draw the airport planners into broader discussions of how the airport's activities will be integrated with—or conflict with—other ongoing, nonaviation transportation plans in the area that may involve modes and developments that are either unrelated (except by proximity) or those that are suitable for direct integration with the plans of the airport's development. Not only will the natural environment be considered in the planning, but such factors as the protection of historic and cultural sites must also be covered.

An environmental impact review (EIR) and environmental impact statement (EIS) are the essential documents that need to be part of any airport planning process. The EIR is a general outline of the potential environmental surrounds, projected impacts, and challenges; the EIS is a more detailed examination that must also include planned mitigation procedures and strategies that will satisfy legal, political, and social requirements. A shorter version of the EIS known as an environmental assessment (EA) can be used in cases where likely impacts to the area can be reasonably expected to be less significant.

Environmental plans and documents, to pass muster with the various federal and local regulatory

agencies, in general must include both mitigation strategies and financial plans to cover the costs associated with putting these strategies into action. An acceptable EA or EIS must list and explain alternatives to the major features of the overall airport plan, so that its eventual environmental impact and mitigation can be assessed within the context of other options to serve the transportation needs of the taxpayers and other constituents.

Today's Tools and Tasks

If flexibility in predictions and response are the keys to successful airport planning, then contemporary planners enjoy an arsenal of technological tools that have been enhanced by several generations of real-world trial and error, as well as contributions from computer simulation experts and aviation's array of professional societies. Decision and options analysis, variable load modeling of factors such as peak-hour flows and queues, data validation, and risk forecasting are among the standard applications that have been shaped into modern airport planning software, guide materials, and practices.

Facing the planner today are projects that span the globe and range in size from small local facilities in high-amenity rural areas to the major new airports in booming metropolitan zones. Reconstruction projects are among the most accessible and rewarding to the up-and-coming airport planner, as the timetables are often compressed and the learning curves steeper. Examples of reconstruction include airline terminal facility makeover, addition of automated people-mover systems, new railroad (including monorail) connections, international passenger customs and security handling facilities, runway reconfigurations, and general passenger building expansion.

Software companies that provide airport planning tools to the industry are cognizant of the need to stay competitive and improve their products by incorporating such developments as newly promulgated FAA advisories, debt financing options from new types of securitization sources and newly initiated taxes and fees, changes in risk acceptance behavior by air carriers, macro-economic trends, and the availability of new construction techniques and more durable materials.

Software packages typically offer modules to assess needs and costs for construction, operations,

and administration. These can be tuned to different scenarios depending on the applications and priorities preferred by management and in light of variables that emanate from outside constituents such as metropolitan and regional elected bodies, allied industries, real estate interests, civic and social interest groups, and the airport-neighbor population.

In preparation for acquiring airport planning knowledge, or in ongoing professional education to update such skills, there are numerous vocational and higher education sources and channels to consider. One validation of a course of study is whether it is offered through the National Center of Excellence for Aviation Operations Research (NEXTOR). The FAA sponsors NEXTOR through its Office of Technology Development and Operations Planning; the program is an alliance with various academic and aviation industry partners. The industry partners are drawn from both the public sector (for example, California Department of Transportation, Maryland Aviation Administration, Massachusetts Port Authority, etc.) and private industry (for example, Boeing, Federal Express, Northrop Grumman Corporation, etc.). Academic core partners as of 2012 included eight major public universities in the United States.

Airport Security

The Transportation Security Administration (TSA) was formed in November 2001 in response to the September 11, 2001, terrorist attacks, in which airplanes were flown into buildings in New York and Washington, D.C. TSA's mission is to conduct security screening of air passengers and luggage. Originally part of the U.S. Department of Transportation, the TSA became part of the Department of Homeland Security on March 9, 2003. Today the TSA faces the dual challenge of increased airline passenger travel and the need to improve the efficiency and effectiveness of screening.

Policy makers and aviation security planners work continually to incorporate into established systems and procedures new technologies that do a better job of detecting security threats. Challenges they face in their efforts to maintain and improve screening functions include optimizing inline explosives detection, streamlining systems for checked baggage, improving the capability to detect explosives at passenger checkpoints, developing strategic plans to improve screening

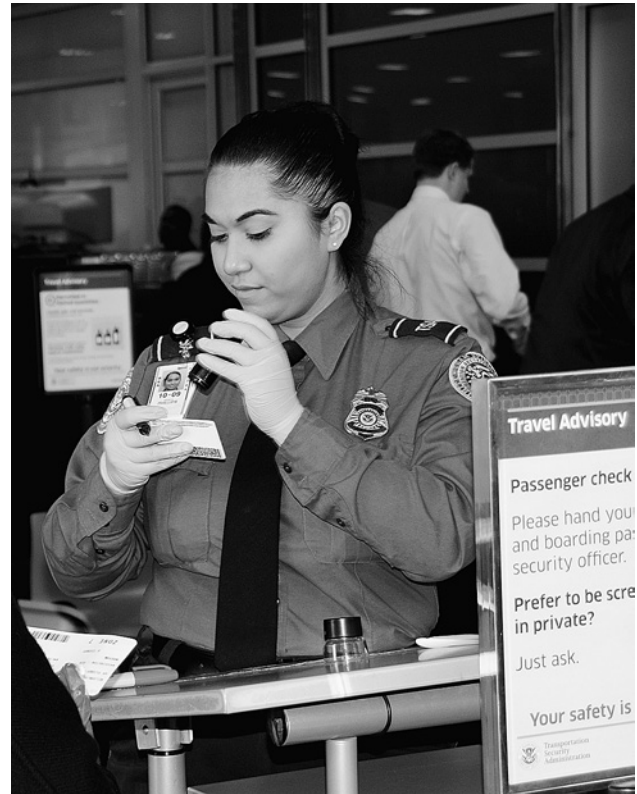

technology, more fully integrating trusted travelers programs, stopping cyberterrorism, maintaining the No Fly List, and possibly arming TSA workers.

Hijackings, bombings, the terrorist attacks of September 11, 2001, when hijacked airplanes were flown into buildings, and universal searches of passengers have permanently altered the nature of air travel worldwide and in the United States. On September 6, 1970, Palestinians hijacked four airplanes, two of which were American, and took 310 hostages. They transferred the majority of hostages to Amman, Jordan, and freed them on September 11, 1970. On September 12, they blew up the empty planes. Responding to this threat, President Richard Nixon placed sky marshals on designated flights to discourage hijackers.

Dan (D. B.) Cooper drew more attention to the problem of airport security when on November 24, 1971, he handed a note to a flight attendant shortly after Northwest flight 305 took off from Portland, Oregon, bound for Seattle, Washington. In the note he demanded a \$200,000 ransom or threatened to blow up the plane with explosives in his bag. Northwest handed over the money, Cooper lowered the stairs at the back of the plane, and he, along with his ransom money, parachuted into infinity. After D. B. Cooper's escape, airplane makers created a Cooper Vane, which made lowering rear stairs during the flight impossible.

Despite President Nixon and perhaps because of D. B. Cooper, the hijackings continued. In December 1972, the Federal Aviation Administration (FAA) mandated that airlines search all passengers and their bags beginning in 1973. Airport security directors installed metal detectors called magnetometers in their airports. It took some time, technology, and court cases for people to become accustomed to magnetometers and for their use to be widespread. Consumer advocates worried about metal detectors and radiation, but studies proved that they gave off scant radiation.

People took the FAA to court, claiming that magnetometers violated the Fourth Amendment, which protects against illegal searches and seizures. The courts ruled that magnetometers were covered by the Fourth Amendment, but they were acceptable as long as their searches were applied universally and limited to looking for weapons and explosives.

A transportation security officer from the Transportation Security Administration (TSA) reviewing passenger identification at a security checkpoint on July 18, 2012.

Baggage Checking

Standards for checked baggage screening were first put into place after plastic explosives hidden in a checked bag blew up Pan Am flight 103 over Lockerbie, Scotland, in December 1988. Since 1997, the FAA has used CAT scans (computed axial tomography imaging) to check bags and baggage at most of America's major airports, including San Francisco International and Hartsfield-Jackson Atlanta International. The CAT scanner is a hollow tube that surrounds a bag and then revolves slowly around it, gathering and recording data by bombarding the bag with X-rays.

Since CAT scanners are slower than other types of baggage scanning systems, security personnel check only the bags that the computer designates as suspicious. An unusual circumstance showing up when a passenger makes reservations or checks in is usually what alerts the computer to flag a piece of luggage. For example, if a passenger buys a one-way ticket and pays cash, the computer responds with a

flag and the passenger's checked bags are immediately sent through the CAT scanner.

Screening passenger baggage is controversial. TSA's policies and personnel have been under scrutiny since the inception of TSA in 2001. The TSA's Office of Investigations and the Homeland Security inspector general's office routinely test the effectiveness of airport screening processes, and some investigations have revealed that actions of some TSA employees often neutralize or erase the safety impact of stringent baggage checking. A 2006 report found several instances of improper collaboration between airport security personnel and TSA officials to warn screeners about undercover tests. A report on undercover operations at Newark Liberty International Airport in October 2006 revealed that screeners had failed 20 of 22 undercover security tests and had missed numerous guns and bombs.

In July 2007, the *Times Union* of Albany, New York, reported that TSA screeners at Albany International Airport failed multiple security tests conducted by the TSA, including missing a fake bomb. In a December 2010 story about a man accidentally taking a forgotten gun through airport security, ABC News Houston said that "the failure rate approaches 70 percent at some major airports." In June 2011, TSA fired 36 Honolulu International Airport screeners for consistently not inspecting bags.

A Government Accountability Office report dated July 30, 2013, citing a 26 percent increase in offenses among TSA employees between 2010 and 2012, seemed to support the public perception and TSA evidence that not all TSA workers are competent or honest. The report cataloged 9,622 offenses by TSA employees; complaints regarding the employees' ethics, integrity, and appearance were recorded, as were 56 cases of theft. Between TSA's inception in 2001 and 2011, approximately 500 screeners (out of 60,000 baggage and passenger screeners) were fired or suspended for stealing from passenger luggage. JFK, LaGuardia, and Newark airports were among the most affected.

Critics have also complained that TSA does not respond properly to thefts and does not reimburse passengers for stolen goods. Passengers who used the Hartsfield-Jackson Atlanta International Airport in 2011 and 2012 reported that the TSA lost or damaged property worth \$300,000 and that the TSA reimbursed only \$35,000 of the claims.

At Jacksonville International Airport, passengers reported \$22,000 worth of goods missing or damaged over a period of 15 months, and the TSA reimbursed only \$800.

The TSA continually evaluates multiple passenger and baggage screening initiatives, including tests of new passenger checkpoint layouts and field testing of next-generation screening technologies. These technologies include machines that detect explosives and chemical traces of explosives, whole-body imaging systems, and advanced technology X-ray capabilities.

Full-Body Image Scanners

Beginning in 2007, governments in many countries, including the United States, began replacing metal detectors with full-body scanners at airports and train stations. In 1992, Steven W. Smith developed the first full-body security scanner called the Secure 1000. He sold the scanner and its patents to Rapiscan Systems, which manufactures and sells the scanner. By November 20, 2010, the TSA reported at least 385 full-body scanners were in use at 68 U.S. airports. The government planned to install 1,000 full-body scanners by the end of 2011, and the government also suggested that it would install full-body scanners in train stations and subways.

A full-body scanner used for security purposes can detect items on a fully clothed person's body without making physical contact. Depending on the technology, the operator can see an alternate wavelength image of a person's naked body or a simple cartoon cutout of the person revealing any suspicious objects. For privacy and security reasons, other passengers generally cannot see the display, and in some places the display is located in a separate room where the operator cannot see the face of the screened person. Full-body scanners can detect nonmetal objects as well.

Taking about 15 seconds, full-body scans are quicker than a strip search, and people do not have to remove their clothes. The analyst sits in a different room and is not supposed to see the person being scanned but is in contact with other security personnel who can stop the scanned person if anything suspicious appears on the scan.

Individuals still have the right to opt out of the scanner and choose a pat-down if the individual is uncomfortable going through the scanner. Individuals also have the right to be patted down in a

private room and have the pat-down witnessed by a person of their choosing.

Sometimes security personnel do a clothes-on pat-down instead of a full-body scan, and a pat-down is often used as a follow-up when a scan detects a suspicious object. In other airports, a full-body scan is mandatory, and if a passenger refuses to be scanned, the airline can bar the passenger from the flight.

Federal law in the United States stipulated that after June 2013, all full-body scanners were required to use Automated Target Recognition software, replacing the picture of a nude body with an image looking more like an avatar or a cartoon. One side effect of the ruling is that the Transportation Security Administration will remove all backscatter X-ray machines since Rapiscan, the manufacturer of the machine, would not be able to meet the deadline.

Passenger Screening and Privacy Concerns

Passenger screenings in airports have taken a central position since four of the five hijackers who flew airplanes into the Pentagon were stopped at Washington Dulles International Airport on the morning of September 11, 2001. They were taken aside after setting off metal detectors but were allowed to continue onto their flight.

Full-body scanners have raised privacy concerns since they were introduced in airports in 2007. Another attempted bombing attack heightened the controversy swirling around the effectiveness of full-body scanners. On December 25, 2009, 23-year-old Umar Farouk Abdulmutallab, a Nigerian who had concealed plastic explosives in his underwear, attempted to detonate them on an international passenger flight from Amsterdam to Detroit Metropolitan Wayne County Airport in Romulus, Michigan. There were 290 people aboard the Northwest Airlines Airbus A30-300, but fortunately Abdulmutallab did not properly detonate the explosives. A Dutch passenger, Jasper Schuringa, restrained him and, with the aid of others, put out the fire while the pilot safely landed the plane.

A Gallup poll taken immediately after the 2009 Christmas Day bombing attempt found that 78 percent of American Airlines travelers approved of body scanners, and 20 percent disapproved. Fifty-one percent of those surveyed said that they would

be uncomfortable with full-body scans, while 48 percent said the idea of full-body scans would not make them uncomfortable. Some people disagreeing with full-body scans said that full-body scanners would not be able to detect the explosives that the “underwear bomber” used in the bombing attempt.

The full-body scanners remained controversial despite the Christmas Day bombing attempt. A Consumerist Web site poll on November 23, 2010, showed that 59.41 percent of people said that they would not fly because of the scan requirements. On November 2, 2010, an MSNBC poll of 8,500 online readers indicated that 84.1 percent believed the scanner would not increase travel safely. On November 15, a CBS telephone poll of 1,137 people showed that 81 percent of those polled approved of TSA’s use of full-body scans.

Privacy and the disposition and legality of the images are major issues associated with full-body scans. Advocates of the full-body scan contend that the head is excluded from the scan and the images are instantly erased, though there are cases where images have been stored and leaked online. Some passengers have objected to having pictures of their naked bodies displayed to screening agents or recorded by the government. Critics call the imaging virtual strip searches without probable cause and they claim the images are illegal and violate basic human rights.

Full-body scanning technology allows screeners to see through clothing to bare skin and to detect prosthetics, including breast prostheses and prosthetic testicles. The scanners also reveal other medical equipment such as colostomy bags and catheters. These discoveries could require potentially embarrassing physical inspections. Travelers have complained that they were singled out for scans or pat-downs because of their gender. Others reported that when they opted not to be scanned they were subjected to invasive pat-downs in their genital areas.

According to one of its documents, *Procurement Specification for Whole Body Imager Devices for Checkpoint Operations*, the TSA, part of the Department of Homeland Security, requires that their full-body scanners export image data in real time, and there are confirmed cases of the government storing images. In August 2010, researchers discovered that the U.S. Marshals Service had saved thousands of images from a millimeter-wave

scanner. Although the TSA insisted that its scanners do not save images and do not have the capability to save images when they are installed in airports, on November 16, 2010, 100 of 35,000 stored body scan images were leaked online and posted by Gizmodo. People opposing full-body scanners have argued that after a successful terrorist attack the machines would not have the capability to save images for later inspection to discover why the scans had not worked.

Opponents of full-body scanners argue that strip searches without probable cause violate basic human rights. They contend that governments do not have the right to make strip searches routine and mandatory, regardless of whether the strip search is done by physically removing clothes or by using technological means to remove the clothes. They argue that full-body scanners and TSA pat-downs are unconstitutional. A study about scanners and pat-downs titled "Full Body Scanners: Full Protection From Terrorist Attacks or Full-On Violation of the Constitution?" came out in the fall 2010 issue of the *University of Denver Transportation Law Journal*. The study argued that the full-body scanners are unconstitutional in the United States because they are too invasive and not effective enough because the methods are too inefficient.

TSA has installed new machines called L3 Millimeter-Wave Body Scanners that show only a generic male or female human form with no features instead of the individual body image that the Rapiscan equipment produced. Nearly 200 of the scanners currently in use in more than 30 airports across America will be removed.

Opponents of full-body scanners still consider the revised scanners an unconstitutional strip search, even though the operators see an edited version of the image. The machine still captures a naked image, and there is no guarantee that the government or private companies will not store the images if a terrorist attack is successful.

Trusted and Untrusted Passengers: Trusted Traveler Programs

Along with the U.S. government and the travel industry, aviation security leaders are developing plans to steadily move into a risk-based system of passenger screening. Government officials who want screeners to focus on travelers who present

more of a security threat support the idea, and they are eager to implement what they call the passenger differentiation concept.

U.S. Customs and Border Protection (CBP) uses a risk-based approach to screen all travelers entering the United States, combining automated advanced data with intelligence and new biometric travel documents. CBP has established expedited "trusted traveler" programs that facilitate entry for frequent travelers who have passed prior screening of their biographical and biometric data. The programs allow preapproved low-risk travelers expedited processing at ports and make it faster and easier for visitors and business people to enter the United States. Expedited traveler programs allow CBP officers additional time to focus on higher risk unknown travelers.

CBP trusted traveler programs include Global Entry, SENTRI, FAST, and NEXUS. At U.S. international airports, prescreened Global Entry members experience expedited entry benefits such as no processing lines, no paperwork, and reduced wait times. Global Entry streamlines airport screening, allowing members to use Global Entry kiosks at select airports to swipe their passports, scan their fingerprints, and make customs declarations without waiting in line.

Collecting and sharing information about passengers is at the center of the risk-based approach. Governments use data that individual passengers have volunteered by applying for trusted traveler programs, as well as information obtained through terrorist watch lists, criminal background checks, and border checkpoint encounters. For passengers on international flights, much of the data in their records is already shared with the Department of Homeland Security (DHS), although DHS has agreed to filter out certain identifying records like meal preferences.

As security measures turn more to identifying trusted and suspect travelers, the federal government is scrutinizing data that airlines and travel agents have collected about their customers, from birth dates and passport numbers to potentially confidential details like travel itineraries or group discount codes. The federal government would also like to employ more behavior detection officers to question passengers in security lines, a technique that Israel uses, although the Government Accountability Office has criticized the way the program

operates in the United States, contending that it has not met scientific standards of validation.

The prospect of using passenger data for airport screening decisions as well as border control had created a divide between European security officials and their American colleagues. As governments and airlines work out the details of distinguishing between trusted travelers, who are eligible for lighter screening, and people who will receive more intense screening, civil liberties groups and some European regulators are questioning the wisdom of using vast amounts of personal data to decide which travelers can be trusted and which cannot be or will not be allowed to fly at all. Although sharing passenger data across borders is already happening, the process presents some complex challenges. Governments have to decide when and how to recognize trusted travelers from different countries and how to deal with nations they do not trust or with unequal human rights issues asking for passenger data.

The TSA has an expedited security program called TSA Pre✓™ and it encourages passengers to apply for global entry to extend eligibility for early check-ins (PreCheck), but some travelers discover to their dismay that applying for trusted traveler status gets them an untrusted label instead. Some people do not have any idea why they were rejected, and other people have been denied because of minor brushes with the law years earlier. If all adults who do have a criminal record—an arrest or a conviction—are rejected, that could exclude millions of people from the trusted traveler pool and hinder the government's goal of including half of all airline passengers in the trusted category.

Travelers who are on the TSA PreCheck Disqualification List can also be excluded. The TSA said that this list would be generated by the TSA Performance and Results Information System, which keeps records of violations of federal, state, local, or international criminal law. It describes the list as a roster of individuals disqualified from eligibility from TSA PreCheck temporarily or permanently because they have violated security regulations. Violations range from getting caught with a loaded firearm at a checkpoint to disobeying aviation security regulations at the airport or onboard aircraft.

When TSA approves a passenger for expedited screening, authorities embed the information in the barcode of the passenger's boarding pass. TSA scans

the barcode at designated checkpoints and the passenger may receive expedited screening. Only Delta Air Lines, United Airlines, and US Airways notified passengers of eligibility on boarding passes in early 2013, but other TSA Pre✓-participating airlines are implementing similar programs.

As civil rights groups and passengers learn more about trusted traveler programs, debates about qualifications, the amount of personal information stored and traded, and implementation and enforcement of the programs will likely become more heated. Some airline experts argue that a system that uses passenger data to assess an individual's security risk should meet important criteria. These criteria include that the system must be proven to effectively capture terrorists, it must identify and capture terrorists without violating privacy rights, and it must avoid negative side effects like discrimination. These are challenging goals for the Transportation Security Administration to meet.

Cyber Terrorism

If cyber terrorists are able to successfully invade one of the U.S. airport systems and cause a problem or shut down operational software that controls all airplane schedules, that single terrorist act may affect other domestic and international airports that are connected to that airport as well as the region where the airport is located. An airport shutdown would cause a ripple effect throughout the domestic and international economy.

Many Pentagon officials believe that terrorists may use strategies intended to eliminate U.S. military technological superiority, but because the U.S. military is significantly supported by civilian technological products and services, including communication systems and electronic and computer software, future conflicts may blur the distinction between civilian and military targets. Terrorists are becoming more adept at using the Internet to communicate with Web sites, chat rooms, and e-mail. They raise funds and covertly gather intelligence on future targets on the Internet. Terrorists are becoming Internet savvy enough to wage a concerted cyber attack against U.S. computer systems.

Most security experts agree that a most likely plan of action for a terrorist group would be to try to disable U.S. computers or communications systems to intensify or supplement a conventional terrorist bombing or other major attack. A

terrorist computer network attack could involve using malicious code as a weapon to infect computers. The code could exploit weaknesses in the software, in the system configuration, or in the computer security systems of an organization or individual user. Another type of terrorist cyber attack is using stolen information to enter restricted computer systems and gain access to their wealth of information.

Cyber attacks by terrorists may prove to be more damaging than physical attacks because they involve disruptive technologies that could produce unpredictable consequences or give the terrorists an unexpected advantage. As in the case of the al Qaeda attacks on the World Trade Center and the Pentagon on September 11, 2001, terrorist physical attacks destroyed important computer databases and disrupted civilian and military operations. Combined with focused and accurate cyber attacks, terrorists could inflict great damage. Most chillingly, cyber terrorists can disrupt communications among the people who must defeat them.

Airline Passengers Versus Blacklists

The United States government had already implemented airport security measures before September 2001, largely in response to the airplane hijackings of the 1970s and 1980s. After the terrorist attacks of 2001, government agencies under the Bush and Obama administrations expanded passenger screening lists, especially after Richard Reid, the shoe bomber, attempted to blow up an American Airlines plane in 2002, and Umar Abdulmutallab, the underwear bomber, nearly detonated a bomb strapped to his underwear on Christmas Day 2009.

For ordinary airline passengers, dealing with lists and their overlaps maintained by government antiterrorism agencies can be as complicated as boarding an airplane. The Intelligence Reform and Terrorism Prevention Act of 2004 established the National Counterterrorism Center, which is a clearinghouse for the various terrorist screening systems and watch lists of the intelligence community and its counterterrorism mission. The National Counterterrorism Center controls a massive database called the Terrorist Identities Datamart Environment (TIDE), including the names of more than 740,000 people. Fewer than 2 percent of them are U.S. citizens or legal permanent residents.

The Terrorist Screening Center of the Federal Bureau of Investigation (FBI) maintains the Terrorist Screening Database (TSDB), which draws much of its data from the National Counterterrorism Center database. In 2010, the TSDB contained information about 423,000 people, about 5 percent of them U.S. citizens and permanent legal residents. The FBI also maintains a smaller list called the Selectee List, which according to 2009 news reports contains the names of 14,000 people who are subject to mandatory airport screenings. The Transportation Security Administration originally oversaw the list but delegated it to the FBI's Terrorist Screening Center.

The Terrorist Watch List

The Terrorist Screening Center maintains a massively larger list than the No Fly List called the Terrorist Watch List, which as of 2011 contained about 400,000 names of people suspected of some involvement with terrorism. By 2013, the list had grown to 875,000 names. The list documents names of convicted terrorists and terrorists at large, registered sex offenders, and people suspected or convicted of drug trafficking.

Critics, including the American Civil Liberties Union (ACLU), contend that the Terrorist Watch List violates individual civil liberties and due process rights because of the possibility of ethnic, religious, political, and economic profiling. Critics say that the Terrorist Watch List is a privacy violation and is based on government secrecy. They argue that determined terrorists can easily circumvent the list by obtaining false identification and other illegal means.

The No Fly List

After September 11, 2001, the Transportation Security Administration (TSA) originally maintained the No Fly List to detain passengers who possibly could be flying somewhere to commit a terrorist act or train in a terrorist camp. Eventually the TSA delegated management of the No Fly List to the FBI's Terrorist Screening Center. The number of names on the No Fly List ebbs and flows with the degree of terrorist threat and amount of intelligence reporting. In 2012, the list contained about 21,000 names including, at one time, that of Senator Edward Kennedy of Massachusetts. The Secondary Screening Selection earmarks

questionable passengers for a second, more thorough screening.

The names of the passengers on the list are not publicized. People are not informed that they are on the list and discover their inclusion only when they are stopped and barred from boarding an airplane or exiting an airport. Several people on the No Fly List have brought suit in federal courts to have their names removed from the list, after being stranded far away from home, since the No Fly List extends to shipping as well. Others have charged that the FBI offered them a deal to become an FBI informant in exchange for removing their name from the list.

In March 2013, the ACLU filed a federal lawsuit in Oregon challenging the constitutionality of the No Fly List on the grounds that the government violated Fifth Amendment due process rights of 13 Americans, including four veterans. The ACLU charges the government placed the passengers on the No Fly List and refused to furnish any explanation or hold a hearing to clear their names. Citing the state secrets doctrine, the government refuses to confirm or deny the presence of names on the No Fly List.

TSA Screeners Versus Terrorists

On Friday, November 1, 2013, Paul Anthony Ciancia, 23, walked into Los Angeles International Airport wearing military fatigues and pulled an assault weapon out of his bag. Opening fire, he killed TSA officer Gerardo Hernandez and wounded two officers and several passengers. Hernandez, a behavioral detection officer trained to look out for suspicious activity, was the first TSA worker to die in the line of duty. His death reignited the debate about the role of airport screeners and how they can protect themselves and the public they serve. Ideas range from giving screeners guns to removing their badges (which resemble police badges). Congress has the power to institute these two changes.

According to some critics, the logistics of providing guns to more than 45,000 officers would be problematic. As of 2013, the federal air marshals were the only TSA officers carrying weapons, and most of them have backgrounds in law enforcement or the military. Arming TSA agents would be time consuming and would introduce weapons into checkpoints where deranged passengers could grab

them and turn them against airport personnel and others. A change in operations would also distract TSA personnel from their mission of finding people and items threatening aircraft.

Airport Transit Connections

The vast and rapid expansion of air transport and the mushrooming of airports have changed the way our society thinks and acts regarding the mobility of people and cargo. Sometimes clashing with and sometimes in concert with the priorities of cities, rural areas, and broad regions containing both, the growth of aviation has raised many questions about how best to tie in civil aviation with surface modes of transportation.

Intermodal Ideals

Ground transport modes, both road and rail, are the great connectors to air transport. Between the two, the highway—and its attendant need to acquire land

for shoulders, ramps, parking facilities, and support structures—has long held the dominant share and made the greatest imprint on airport ground-link planning and practice. However, the very popularity of air travel and transport has led to overcapacity, delays, and congestion on the ground, as limits have been reached for automotive and trucking options.

Congestion, air and noise pollution, and community resistance to land-acquisition policies have led many municipalities, counties, and regional planning authorities to consider rail links between urban centers, suburban and rural areas, and the airports that serve them. This movement has been echoed at the national level.

The construction of monorails, light rail connectors, and intercity rail links, including the main U.S.-based passenger carrier, Amtrak, has increased in the last two decades. Many large cities—New York and Washington, D.C., in the United States; Osaka and Tokyo in Japan; Paris and Frankfurt in Europe to name a few—have established effective rail links to their major airports, with continuing success as gauged by such metrics as usage trends, safety, energy savings, and return on investment.

At the same time, there are multiple ways to improve the handling of highway-based transit to and from airports; this mode will certainly be the first choice for many years to come in most localities. Therefore, the design, planning, and improvement of such efficiency-raising, congestion-cutting concepts as park-and-ride, subsidized shuttle bus service, adaptable traffic flow control systems, advanced people-moving technology in and around terminals, and related ideas will continue to grow in importance. Metropolitan and regional planners need to consider and adapt each of these in turn; they are supported in this by advocacy from within the aviation industry, as well as from citizens groups and from various federal measures.

Leading by Legislating

In crafting the Federal Aviation Administration (FAA) Modernization and Reform Act of 2012, legislators working with the chief administrators of the FAA moved to relax some standing restrictions on the use of airport passenger facility charge (PFC) revenues, specifically so as to enable airports to invest in transit connection infrastructure such as intermodal staging areas, including rail links to urban areas and intercity destinations.

A sign for a light rail transit connection in Terminal 1 of the Salt Lake City International Airport in Utah in July 2013. Rail links have grown increasingly popular in planning for U.S. airports.

The FAA and its congressional sponsors sought to support “airport and intercity passenger rail operations that can improve connectivity between airports and intercity passenger rail facilities and stations,” and even to find ways to defray the costs and enhance the benefits “of the implementation of more integrated scheduling between airlines and Amtrak or other intercity passenger rail carriers achieved through code sharing arrangements.”

The authors of the FAA bill emphasized that there already were a range of related legislative bills under consideration in the U.S. House and Senate that would, among other goals, streamline administrative requirements so as to encourage airport authorities to impose new PFCs “to finance an intermodal ground facility” and initiate a program to construct “off-airport intermodal ground access projects related to movement of airport passengers” and goods.

In a similar vein, the White House, through its National Aeronautics Research and Development Plan of 2010, in its section on improving fundamental mobility in air transport, pointed to the need to develop “airport terminal designs that facilitate passenger throughput, including movement between surface and air transportation modes.”

Initiatives like these built upon more longstanding laws and funding structures. One such was the Intermodal Surface Transportation Act of 1991 (ISTEA), which shifted federally supported transportation planning from what had been a virtually all-highways focus to a new vision of an integrated and fully intermodal transportation system. ISTEA altered reimbursement rates to states engaged in various major transit projects, seeking to influence capital outlays toward this new vision.

A result of the establishment of ISTEA was to strengthen metropolitan planning organizations (MPOs) by mandating their participation in various project selection roles. This mandate, along with increased direct funding of MPOs by the U.S. Department of Transportation, has tended to enhance the abilities of MPOs to partner across regions and to negotiate with airports, port facilities, and other transit and transportation decision-making businesses and bodies. Along with these actions, ISTEA required major urban areas to develop long-range transportation plans entailing much public comment, ensuring considerable focus on environmental and zoning issues, and embodying the new intermodal ideals.

There is reason to be optimistic that both commercial interests and public administrators can see eye-to-eye on the issues of airport–transit connections and will develop improved ways to plan and construct smart solutions.

studied in terms of conflicts between animals and aircraft, with less known about the effects of airports on habitats and specific species. Reducing the effects of noise involves either reducing it at the source through quieter engines or changes in operations (known as abatement), or reducing its effects through land use controls or by soundproofing existing structures (known as mitigation). Air pollution is mitigated through source reduction, both of aircraft and ground vehicles. At some point, however, without further technological improvements, the only mitigation that is possible within the constraints of current technology is to reduce (or at least not increase) the number of flights, leading to the question of how much more expansion of airport infrastructure is possible in certain locations.

Noise Pollution

Noise exposure is determined for individual airports by averaging aircraft noise over a 24-hour period to produce DNL (Day-Night Level) contours, measured in decibels. Normal conversation takes place at a level of about 60 dB, which implies that living in an area at or above the 65 DNL would make conversation extremely difficult. Because the noise contours are averages, however, this means that periods of quiet alternate with sound levels up to 100 dB when a plane passes overhead, resulting in an average of 65 DNL. Noise lines are mapped out as contours similar to a topographic map, usually drawn at the 75, 70, and 65 DNL levels, and no contour higher than the 75 DNL usually extends beyond airport property. DNL levels are assessed via computer modeling, including data on the mix of aircraft at a particular airport, how noisy those aircraft are, how many operations there are per day, and the height of the flight paths. These same factors are then projected five or more years into the future, thus requiring input from airlines as to their future operations. Noise between 10 P.M. and 7 A.M. is given a weight of 10 extra decibels due to less background noise and the fact that most residents are sleeping. Since the decibel scale is logarithmic, this means that nighttime flights (or "events") are considered 10 times as noisy as daytime ones. The levels may be checked via sound monitoring, or the computer projections may be used without ground verification.

Within the United States, the Federal Aviation Administration (FAA) and Environmental

Airports, Environmental Issues and

The environmental effects of airports are often considered to be externalities or side effects that can be alleviated by some sort of mitigation. Increasingly, however, environmental externalities are feeding back into the system, affecting the expansion of airport infrastructure. It seems likely that the magnitude of aircraft movements will increasingly be determined by where citizen opposition on environmental grounds is minimal, which makes it necessary to understand what those environmental limits might be.

There are three main types of environmental effects from airports: noise and its consequences for the human environment, air pollution at local and global scales, and impacts on wildlife. Noise has been well studied in terms of its effects on health (minimal) and property values (small but significant), air pollution has been shown to have significant impacts on health and well-being in the airport vicinity, and wildlife impacts have mostly been

Protection Agency (EPA) have agreed that residential land uses are officially incompatible with airport operations within the 65 DNL contour. About 5 million people within the United States lived within such a line in 1990, although after international restrictions on aircraft noise went into effect in 1990, that number dropped to 323,000. The FAA's official policy is that land use planning should be left up to local communities, with safety restrictions on height and population density the only exceptions. However, even in communities where the airport is taken into account in land use planning by locating residential development outside the noise contours, future runway configurations can negate such planning by changing those contours and exposing new populations to noise, as seen recently in Minneapolis–St. Paul and Chicago.

There are two main sets of concerns about the effects of aircraft noise on residents: health risks and property values. Differing physical, psychological, and socioeconomic characteristics mean that the same level of noise can affect individuals quite differently. Nevertheless, there is strong evidence that sleep patterns and concentration are disrupted and that quality of life and health can be reduced up to 10 miles from the airport, or over three times as far as the 65 dB noise contour extends. At the same time, there is a general consensus that aircraft noise lowers residential property values: an average decrease in property values from 0.4 to 1.1 percent occurs for every 1-dB increase in DNL. In other words, a house located in the 64 DNL contour is worth between roughly half a percent to a percent less than if it were located in the 63 DNL contour.

Noise Reduction

Reduction of aircraft noise can be provided in one of three ways: mitigating the effects of the noise, as with soundproofing; abating noise at the source via technology; or changing flight operations. Many airports use all three methods. Because of concern over lost property values due to aircraft noise, the FAA will fund mitigation to residences and other buildings deemed incompatible with this noise level, partially via passenger facility charges (PFCs) attached to airline tickets. Approximately 70 percent of these funds go to the acquisition of property and relocation of individuals, while nearly 20 percent go toward soundproofing. Only 3.4 percent of these funds go toward planning to

prevent noise incompatibilities in advance via land use planning or land acquisition. Soundproofing is generally preferred by residents over relocation because they are able to stay in their neighborhoods, by cities because of the maintenance of neighborhoods and tax base, and by airport operators because of the lower cost and less disruption to neighborhoods.

Source reduction of noise, of course, is the mitigation method preferred by residents but opposed by airlines, leaving airport operators often caught in the middle. There are two ways to reduce the noise heard on the ground: operations changes, such as flight tracks that take aircraft over nonresidential land uses, or changes to the aircraft themselves to make them quieter. Operations changes are generally considered voluntary, since the pilot has ultimate control over where his or her plane flies once it is in the air. Frequent communication is thus required between the air traffic control tower (managed by the FAA) and the airport operator (in the U.S. context, usually a local unit of government or independent regional authority) to make sure the operational changes are being implemented. Operations changes often simply redirect noise to another area, spreading out the effects rather than reducing them and potentially pitting airport neighbors against each other.

Aircraft themselves are the most permanent site of noise reduction, and as new technology has been made available, the sound produced by individual aircraft has decreased dramatically. For example, one of the first long-haul jet aircraft was the Boeing 707. On takeoff, a 707 creates a one-time exposure of 65 dB or higher to an area covering 82 square miles. The comparably sized 757, introduced in the early 1980s, exposes only 14 square miles to the same sound level, while Boeing's new 787 has a footprint of only 0.7 square miles. This tremendous decrease, however, is offset at many airports by the tripling in air traffic that has taken place over the same time period.

The model that is used to determine the DNL contours is more sensitive to noise than to frequency, so the contours have generally grown smaller with time. However, residents may be equally sensitive to the level of noise and the number of noise events (that is, flights), making the DNL method an increasingly less accurate reflection of the level to which residents are affected by

A Boeing 747 descends over a residential area on approach to Heathrow Airport outside of London, England, in July 2004. Advancements in aircraft noise reduction have been offset by a significant increase in air traffic since the 1980s.

airport noise. Other methods, such as measuring the minutes in the day during which noise exceeds the 65 dB limit, could more accurately reflect the impact on the human environment.

Air Pollution

Air pollution is increasingly becoming a concern of both airport neighbors and the larger community. Airport pollution comes from three sources: groundside traffic such as cars and trucks, taxiing or idling aircraft, and overflights. At the local level, airports are often given exemptions from state and federal emissions laws, despite the fact that they can be among the highest polluting facilities in a state. Nor are airports required to report their toxic emissions totals in the National Toxic Release Inventory. Pollution at a global level may be an even greater cause for concern because emissions at high altitude have a more direct effect on global warming than those at ground level.

There are three main types of pollutants produced by aircraft engines: oxides of nitrogen (NO_x), carbon monoxide (CO), and hydrocarbons or volatile organic compounds (VOCs). Most NO_x emissions are actually produced by motor vehicles, though NO_x is the

primary pollutant produced during the high-power maneuvers of takeoffs and cruising. VOCs and CO predominate during low-power operations such as taxiing, meaning that delays on the ground translate to more emissions of these compounds into nearby areas. Both of these types of emissions are actually decreasing around major airports because of technological changes. However, in an ironic trade-off, the changes that enabled engines to be quiet enough to meet new requirements for noise also mean that those engines produce more NO_x .

Though it can be difficult to separate the effects of background urban pollution from that emitted by the airport, a number of studies indicate that proximity to a major airport does result in some increased health risks. A study commissioned by Park Ridge, Illinois, for example, found a higher cancer risk than is considered acceptable under federal standards for residents not only in municipalities adjacent to O'Hare International Airport but for 98 total municipalities in the metropolitan area. A study in New York chose the cutoff point of 5 miles away from an airport and found that living within this distance led to an increased risk of hospital admissions for respiratory conditions. Finally, because jet fuel is not unleaded, elevated levels of lead in children's blood have also been observed near major airports, including a 2.1 percent increase within a mile and up to a 4.4 percent increase within a third of a mile.

At the same time, studies on increased cancer rates in airport-adjacent neighborhoods have been largely inconclusive. Though most studies have shown that emissions in the area of airports are no worse than in urban areas in general, one exception is a study commissioned by the town of Winthrop, Massachusetts. Winthrop is located at the end of a peninsula in Boston Harbor, so that the only emissions come from residential auto trips—and aircraft. Here, the study did find a correlation between residents' proximity to Boston Logan International Airport and the incidence of respiratory diseases, suggesting that were it possible to more carefully parse out air pollution from the airport itself as compared to its surroundings, the effects on human health might be more noticeable.

Impacts on Wildlife

The bulk of the research on the environmental impacts of airports regarding wildlife has to do with

their interference with aircraft. Between 1990 and 2009, there were 99,411 animal strikes reported in the United States to the FAA from 77 different species. While bird strikes are the best known, particularly after US Airways Flight 1549 crash-landed into the Hudson River in 2009, an analysis of these data indicates that deer and dogs are actually the most hazardous when considering the likelihood of damage to the aircraft. Of bird species, geese are the most hazardous because of their size, with vultures posing significant problems as well because of their propensity to fly at higher altitudes. It is important to note that the specific ecological conditions of a particular airport and its surroundings need to be considered when determining the threat that wildlife pose to aircraft and the possible ways to mitigate that threat.

The primary means of reducing the hazards that wildlife pose is by making the airport and its surroundings as unattractive to wildlife as possible, which therefore comprises the main environmental impacts of airports on wildlife. For example, the deliberate removal of wetlands to discourage birds and other species from nesting or feeding (aside from wetland removal associated with airport construction) is a common management practice. Other types of land uses such as landfills and agricultural fields that are known to attract birds are therefore also undesirable, even though these land uses have high noise compatibility with airport operations compared to residential or commercial land. At the same time, management techniques such as frequent grass mowing to discourage bird nesting may make that same habitat more attractive to other species that prefer short grass, meaning that trade-offs need to be considered in airport environmental management.

Aside from their habitat being altered or removed to reduce the risk they pose to aircraft, there are other impacts on the ecological conditions in the airport vicinity coming from the contamination of soil and water, potentially stretching miles beyond airport borders. Studies have found lead, cadmium, per- and polyfluorinated compounds (PFCs), polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), benzotriazole, and tolyltriazole, all of which have been classified as either toxic or probable carcinogens, to be present in significant amounts in soil and/or water adjacent to or downstream from major airports.

Depending on the climate, significant amounts of propylene glycol may be used to de-ice aircraft, and potassium acetate or urea may be used to keep taxiways and runways from freezing over. Both of these chemicals run off into waterways as well. Fuel storage units can leak or spilled fuel can wash off aprons and taxiways, as can chemicals from fire-fighting equipment from drills or actual incidents. Because of the hazardous nature of any liquids on airport pavement, airport pavement systems are designed to quickly remove surface runoff, although such systems will contaminate groundwater if they leak.

The implications for wildlife of these environmental contaminants can be significant, although relatively little research has been done in this regard. For example, one study in Milwaukee found that 40 percent of the water samples taken downstream of the airport exceeded the toxicity point for aquatic life. An Italian study showed that honeybees near Rome's Ciampino Airport accumulated the highest lead levels of any bees sampled in the region, probably from jet fuel fumes or contaminated soil. Since many airports are only just beginning to monitor the extent to which their operations contaminate surrounding water or soil, much research remains to be done on the impacts to wildlife.

Alternative Automotive Fuels

Alternative fuels (AF) can be defined as substitutes for conventional fuels relying on hydrocarbons and petroleum. They come from non-crude oil resources and include all vehicular fuels other than diesel fuels and gasoline. Traditional fuels have been the primary automotive fuels used since the early part of the 20th century. In recent years oil has supplied as much as 96 percent of the fuel for the U.S. transportation fleet. The United States burns about 13 million barrels of oil a day for its transportation system. Transportation represents about 70 percent of U.S. oil consumption and 30 percent of U.S. greenhouse gas emissions, with gasoline and oil fuels accounting for 60 percent of oil consumption.

Types

The most commonly used alternative fuels for transportation are first-generation liquid biofuels/agrofuels (for example, ethanol and biodiesel). The term *biofuels* also includes fuels derived from forests such as wood and charcoal, while the term *agrofuels*

derives from nonforestry activity, including agricultural crops. Agrofuels/biofuels are fuels obtained as a product of energy crops and/or agricultural by-products, fuel crops, wood or herbaceous crops grown specifically for their fuel value. Second-generation liquid biofuels are produced from nonedible parts of agricultural feed stock such as husks and hay. While some support production of ethanol and diesel from agricultural waste products and nonedible plant material, this is not yet being done on a large scale. Third-generation liquid biofuels are composed of other organic material, such as algae cultivated for this purpose. Fourth-generation liquid biofuels result from the use of microorganisms and carbon monoxide to generate fuel.

Although conventional fuels still comprise the majority of the fuels consumed in the transport industry, AF are on the rise. Countries like Brazil, Italy, and New Zealand have developed vehicle transportation systems based on AF. In 2004, 50 percent of Brazilian cars ran on bioethanol and in 2007 the number was 80 percent. In the United States, recent proposals from the Barack Obama administration included using \$2 billion in funding coming from federal gas and oil royalties over a 10-year period to pay for research supporting AF cars. The goal of this plan was to support replacements for hydrocarbons as the primary fuel used by cars, trucks, and buses. The Obama administration and others have argued that AF are cheaper, more sustainable, and can promote energy security, freeing countries from depending on nations supplying oil that are considered unstable, in conflict zones, or less democratic.

In general, attempts are being made to reduce emissions from gasoline and diesel as well as to develop AFs. The lead additives in gasoline have been banned in almost all countries. As a substitute for such additives, oxygenated supplements like ethanol and methanol have been used. Mukesh Khare and Ptrateek Sharma explain that "the commonly used oxygenate in gasoline blends are methanol, ethanol, t-butyl alcohol (TBA), methyl t-butyl ether (MTBE), and ethyl t-butyl ether (ETBE)." Oxygenated gasoline can reduce carbon monoxide (CO) and hydrocarbon (HC) emissions, have a higher octane rating, and lower emissions from older vehicles. Some "reformulated gasoline" (RFG) may lack oxygenates, although the terms have been used interchangeably. Gasoline is reformulated to both reduce evaporative emissions

(or volatility) and sulfur. Reformulated gasoline can reduce nonmethane HCs in contrast to fuels only using HC. In the United States, Congress mandated the RFG program in the 1990 Clean Air Act amendments. RFG is mandated in cities with high levels of smog, currently used in 17 states and the District of Columbia. Recent estimates state that about 30 percent of gasoline sold in the United States was reformulated. The Environmental Protection Agency (EPA) reports RFG has contributed to reduced smog levels and “about 75 million people breathe cleaner air because of RFG.”

Biodiesel is a kind of AF using renewable resources that can safely be used in any modern diesel engine. Biodiesel is usually produced from oil-producing plants like rape seed, oil palms, soybeans, sunflowers, and jatropha. Vegetable oil is pressed from oleaginous/oleiferous (oil-rich) plants and

converted through a process called esterification; it can also be made from waste cooking oil. Biodiesel initiatives have been started in almost every country in the world.

Fat can be transformed into fuel, recovering energy and recycling wastes that otherwise might have been flushed down drains or dumped in landfills. Diesel provides low output per kilogram and liter, creating higher initial costs. Yet, it still provides lower overall operational costs. David Sandalow explains that “diesel engines are 30 percent to 40 percent more fuel efficient than comparable gasoline engines.” In the past, the use of such engines in the United States has “been limited by dirty exhaust and a reputation for poor quality,” but improvements are under way. Diesel engines perform “especially well carrying heavy loads at low speed” and “are used widely in large trucks and heavy equipment.” They have “better torque and greater durability than gasoline engines.” The Worldwatch Institute in Washington, D.C., suggested that biofuels could provide 37 percent of transportation fuel used in the United States within the next 25 years. With a doubling of automobile fuel economy, such fuels could provide 75 percent of such fuel. In contrast, the U.S. Energy Information Administration has discussed scenarios involving a far more modest reduction in fossil fuels.

Environmental Principles

Sustainability can be assessed based on the environmental, social, and gendered impacts of different fuels, with impacts related to the quantity of potential damage to the ecosystem and the qualitative impacts of different fuels. Christopher Knittel reports several environmental costs associated with burning petroleum: “The transportation sector accounts for 67 percent of carbon monoxide emissions, 45 percent of nitrogen oxide emissions ... and 8 percent of particulate matter emissions.” This leads to health problems, smog, and infant mortality. The burning of “a gallon of gasoline causes roughly 25 pounds of carbon dioxide to be emitted into the atmosphere, which raises the risks of destructive climate change.” Some of the health effects of pollutants in conventionally fueled vehicles include a reduction in the capacity of the blood to transport available oxygen to tissues (from CO), an increase in the vulnerability to respiratory infection (from nitrogen oxide),

A student technician with the U.S. Department of Agriculture compares soil solution samples to be used in biofuel crop research. Jatropha is one plant being considered as a possible future feedstock for biofuel production.

and various toxic and carcinogenic effects (from hydrocarbons).

In assessing the environmental impacts of alternative fuels, various principles must be considered. First, some AFs are more ecologically sustainable than others. In other words, even if a fuel source is classified as an AF, it does not necessarily have to be sustainable. Khare and Sharma note, “a decrease in the aromatic content of gasoline may lower carbon monoxide ... and hydrocarbon ... emissions but may increase nitrogen oxide ... emissions.” Yet, “a major advantage of fuel modification is that it often can take effect quickly and begin reducing pollutant emissions immediately.” AFs can emit toxic organic compounds, including benzene, toluene, 1,3-butadiene, formaldehyde, and acrolein. Biodiesel is non-toxic and biodegradable, however. The ability of a vehicle using AF to produce low pollutant emissions can depend on how much pollution control equipment is deployed.

Second, the efficiency regime can influence outcomes. Greater growth can wipe out a portion of sustainability gains from using a less polluting fuel. For example, given the “Jevons paradox,” lowering prices of fuels may increase their use, thus potentially lowering the sustainability advantages of AF. For example, if fuel A is 50 percent cleaner than petroleum (fuel B), substantial increase in the use of cars and other vehicles can wipe out the aggregate advantages coming from using fuel A rather than fuel B. In the United States, travel on all roads and streets was 1,933,289 million vehicle miles, increasing to a peak of 3,030,794 million miles in 2008 (the year of the latest financial crisis), but decreased to 2,948,804 million miles in 2012. In general, AFs have a lower energy density, requiring greater onboard storage than diesel or gasoline. Yet, some AFs provide more energy per kilogram than gasoline, so AFs can be more efficient.

Given these potential constraints, some point to the use of electricity driven by more sustainable and less damaging sources as a supplement, if not an alternative to AFs.

Bioethanol

Bioethanol is essentially alcohol made from agricultural raw material called feedstock. Bioethanol is usually made from sugarcane, maize, wheat, sugar beets, sorghum, and starchy tubers like cassava. Ethanol can be made from any biological

material, but sugary crops are easiest to ferment. Ethanol is the most widely used biofuel, sourced primarily from corn, in the United States. In contrast, sugarcane is the main feedstock used in Brazil, with Louisiana supplying this crop as well. Cellulose is another source for ethanol and can come from waste paper, agriculture residue, and switchgrass. Ethanol is cleaner, less toxic, and less corrosive than methanol. Carbon monoxide and nitrous oxide are lower in ethanol than gasoline. Yet, some claim that producing ethanol may increase carbon dioxide. Ethanol emits 70 percent to 75 percent less CO₂ compared to petrol/gasoline during combustion, but the effect has been disputed by those examining the entirety of the production and distribution system. Ethanol is a widely contested biofuel because of its sourcing from edible raw material. To fill the tank of an SUV with ethanol takes 450 pounds (20 kilograms) of corn—the equivalent of one person’s total caloric need for a whole year.

In reviewing various studies, Knittel reports one that found that the use of Brazilian sugarcane ethanol could reduce pasturelands, leading cattle farmers to cut down rain forests. Thus, “once indirect land use effects are considered, corn-based ethanol can have nearly twice the greenhouse gas emissions of gasoline.” Another study Knittel cites found that “once changes in both international trade and crop yields are accounted for, corn ethanol results in fewer greenhouse gas emissions than gasoline, despite indirect land use changes.” The Global Studies Initiative has raised questions about how biofuel consumption could displace land and markets used to produce food, animal feed, and a smaller volume of industrial products. Women are more vulnerable than men to the effects of displacement because they often lack land tenure and access to both agricultural inputs and markets.

Ethanol can be used as the principal fuel in a vehicle as in E85 (85 percent ethanol and 15 percent gasoline) or primarily as a supplement, as in E10 (90 percent gasoline and 10 percent ethanol). With a lower heat value than gasoline, more ethanol is needed than gasoline to drive a vehicle an equivalent distance. Some engineers interviewed by *Consumer Reports* said that “E85 fuel economy could approach that of gasoline if manufacturers optimized engines for that fuel.” *Consumer Reports* notes a study by David Pimentel at Cornell

University stating that the growth of corn and its transformation into ethanol required 30 percent more energy than the ethanol contains. In contrast, Michael Wang at Argonne National Laboratories says ethanol produces 35 percent more energy than required by its production process.

A report in the *New York Times* on March 16, 2013, notes that “nearly 10 percent of the nation’s ethanol plants have stopped production over the past year, in part because the drought that has ravaged much of the nation’s crops pushed commodity prices so high that ethanol has become too expensive to produce.” In addition, “blends calling for a higher percentage of ethanol have yet to catch on widely in the marketplace.”

The congressional goal to promote E10 was based on the assumption of increased demand for fuel. Yet, this demand has gone from 9.7 million barrels a day in 2007 to only 8.7 million barrels in 2013. With corporate fuel economy standards expected to double average mileage by 2025, this suppresses oil demand (which could rise with population growth).

Biodiesel

Biodiesel is produced by reacting animal or vegetable fats with ethanol or methanol, creating a fuel that is similar to diesel in its physical characteristics. Khare and Sharma cite the study by Salvatore Alfuso and colleagues suggesting “higher particulate emissions in comparison with conventional diesel fuel” and costs that are “substantially higher than conventional diesel.” Yet, a later (1998) biodiesel life cycle study jointly sponsored by the Departments of Energy and Agriculture argued that emissions can be much lower than those coming from a petroleum-powered vehicle, with up to 78 percent less carbon dioxide. The CO₂ released from burned biodiesel can be recycled by growing plants. Nevertheless, use of the fuel burns hydrocarbons and contributes to greenhouse gases, albeit at much lower levels.

The use of government subsidies reduced biodiesel costs in the United States at one point such that costs were equivalent to gasoline. The U.S. Congress provided a retroactive reinstatement of a dollar-a-gallon credit in January 2013, amounting to about one-fourth of the fuel’s then current wholesale price. According to the National Biodiesel Board, production of the fuel has dramatically increased in recent years: from 2 million gallons in 2000 to 225 million in 2006 and more than 1 billion gallons in 2011.

Jason Hill and colleagues compared these two fuels in 2006, suggesting neither could “replace much petroleum without impacting food supplies.” They noted, “ethanol yields 25 percent more energy than the energy invested in production, whereas biodiesel yields 93 percent more.” Moreover, “relative to the fossil fuels they displace, greenhouse gas emissions are reduced 12 percent by the production and combustion of ethanol and 41 percent by biodiesel.” According to Wim Soetaert and Erick Vandamme, the production of vegetable oils cannot increase to meet the demand for biodiesel so competition with the food market is inevitable.

Jatropha is viewed by some observers as a very promising biofuel feedstock. *Jatropha curcas* L. (Barbados nut or pourghere plant) is a succulent plant originating in South America. The plant produces golf ball-sized nonedible, oil-rich seeds that are used mainly for medicinal purposes, to make soap, and as fuel for lamps. The jatropha bush produces a fruit containing a milky, yellowish liquid similar to that of palm oil, which can be used to make biodiesel.

Jatropha as an agrocrop for biodiesel production has attracted enormous attention in the last years especially after Goldman and Sachs proclaimed it to be one of the two most promising agrocrops. A British-based company has started an initiative to crop jatropha along train tracks in India, on mining-degraded land in the Philippines, and on a dumping ground for wastewater in Egypt.

Leonardo da Vinci made sketches of self-propelled wagons. A few centuries later, inventor Nicolas-Joseph Cugnot brought the dream to fruition with a steam-powered vehicle generally called the first automobile. This was followed by Karl Benz's development of the original gasoline-powered car, which used an internal combustion engine.

Benz's car served as the archetype for all internal combustion engine vehicles that came after it. His company, now known as Mercedes-Benz, went into production in Germany. Less than 15 years later, the Ford Motor Company was started in the United States and the era of the automobile had begun. Throughout the 20th century, additional car manufacturers started up in Europe, Asia, and the United States. The source of power for almost all of the vehicles produced remained the same: gasoline-powered internal combustion engines.

The Use of Fossil Fuels

Internal combustion engines get their name from their combustion of fossil fuels, specifically gasoline. Used efficiently, the process converts gas into mechanical energy, powering the vehicle. Unfortunately, the process also sends a substantial volume of polluting by-products out into the air through an exhaust pipe. In addition to carbon dioxide (CO₂) and water vapor, the by-products include carbon monoxide, benzene, and nitrogen oxide (NO_x). Sulfur dioxide (SO₂) may also be emitted due to gasoline impurities. These by-products adversely affect air quality by increasing smog, which particularly correlates to SO₂. Greenhouse gases like CO₂ also contribute to global warming. Nitrogen oxide is a factor in acid rain.

Because of these negative effects from using gasoline to power internal combustion engines, many people want to use alternative fuels for their cars and trucks instead. Their hope is that these will pollute less, helping protect the environment. There are many different kinds of alternative fuels that can be used to power automobiles.

Biodiesel

Some vehicles have compression ignition engines, also called diesel engines, which do not require a spark for ignition. They have a high rate of thermal efficiency compared to nondiesel internal combustion engines (ICEs). Because of that, they maximize the amount of mechanical energy that can be derived

Alternative Fuels

The idea of mechanical vehicles for roads once dominated by horses is an old one. It dates back to at least the 15th century, when famed artist

from a given amount of fuel. Typically, the rate of conversion is 45 percent. That contrasts to regular ICEs using gasoline, which only have a 30 percent conversion rate. Additionally, diesel engines using fossil fuels have only minimal CO₂ output in exhaust but do produce substantial amounts of nitrogen oxides when using fuel distilled from petroleum. That problem can be moderated by incorporating an alternative fuel called biodiesel.

Biodiesel is based on a lipid such as vegetable oil or tallow. Fatty acid esters are produced when the base substance is reacted with an alcohol, producing the mono-alkyl ester used for fuel. In standard diesel engines, biodiesel is not used exclusively. Instead, it is combined with petroleum-derived fuels in various percentages. For example, if the fuel used is 20 percent biodiesel and 80 percent sourced from petroleum, it would be labeled B20 (meaning biodiesel 20 percent). Using B100 (100 percent biodiesel with no petroleum-based constituents) can necessitate modifications to the diesel engine being used for the process to operate at peak efficiency.

Of course, higher percentages of biodiesel correlate to greater shares of the benefits this alternative fuel provides. One of those benefits is a decreased reliance on Middle Eastern sources of fossil fuels. That helps the United States become more energy independent and secure from the risk that geopolitical conflicts pose to fossil fuel supplies.

Another benefit is the lowering of greenhouse gas emissions, since use of vegetable oil based biodiesel is much less polluting than the use of fossil fuels. Because consumers have become more environmentally conscious over the past decade, lessening pollution is a major selling point to many.

Yet, using vegetable oil for this purpose is connected to a related debate about food versus fuel. The concern is that if too many farmers focus on raising crops that will be used in fuel production, they will raise less that are used for food. That dynamic can affect food supplies and raise prices. Fortunately, targeted crop production is not the only source of biodiesel.

Biodiesel fuel can also incorporate waste vegetable oil, also called UVO to indicate that it was already used for unrelated reasons. Industrial deep fryers typically found in food processing plants and restaurants produce 2.9 billion gallons of UVO per year. If recycled, it can be used in modified diesel engines as a fuel source. This option has gained substantial

publicity, as it makes use of waste material that might otherwise simply be disposed of. It also requires no additional use of farmable land, negating the objections directed at raising crops for fuel purposes.

Other sources of biodiesel include animal fat. While this also includes use of farmland, it is land that would be used for raising animals anyway. Those animals would typically be raised for meat, and the associated fat can be converted to fuel. Fish oil is an additional source, and it is derived from Omega-3 fatty acids production process.

An emerging source is called Salicornia. It is a salt-tolerant plant that can be grown in areas unsuitable for regular crops, including in marshes and even on beaches. It offers direct benefit to the areas in which it grows by filtering carbon dioxide from the air. Salicornia also produce seeds with a high concentration of unsaturated oil that is viable for biofuel purposes. This combination of traits is drawing substantial investment interest from around the world. Salicornia fields are the newest and potentially most promising biodiesel source, since the land in which they are grown would not support other crops anyway. With up to 250 gallons of fuel produced per hectare of Salicornia, it is a cost-effective, profitable, and environmentally responsible fuel source.

Ammonia

Another option currently being explored is ammonia, which is a gas composed of three parts hydrogen for every one part nitrogen. Tests have shown that it can be used in modified versions of internal combustion engines and diesel engines. This flexibility makes it an attractive possibility in that it could be used in current cars after modest alterations were made to their engine systems.

The approach with ammonia involves using it as a supplement to gasoline, allowing less gasoline to be used. First, a separate tank for the liquefied ammonia is added to a vehicle. The car is started with gasoline, and while the engine is idling, ammonia is added. This provides additional energy to the vehicle. Because ammonia has only half the energy of gas for equivalent volumes, vehicles equipped with these systems can switch back to using only gas when needed.

The combustion by-products of ammonia are simply water vapor and nitrogen. The absence of carbon-based pollutants, such as those emitted when using gasoline, is ammonia's major

selling point. In vehicles that use both fuels, there is an inverse relationship between them: the more ammonia used, the less gasoline used, resulting in less harmful exhaust.

Wood Gas

In World War II, the ramifications of war compromised oil and gas supplies for domestic consumers. By that point in history, however, the car had already become a staple of American life. Individuals still wanted to drive to their offices, homes, and shopping centers. Instead of giving up that desire, they came up with a very clever alternative.

Wood gas cars were built so people could get where they needed to go despite oil and gasoline shortages. They used the wood that otherwise would have gone into fireplaces to provide warmth.

The wood is placed in a wood gas generator, typically attached to the back of a vehicle. Putting it in the bed of a truck was common. Heat is used in the oxygen-limited environment of the generator, producing gases that can be used to power vehicles. Since wood was in plentiful supply at affordable prices, it seemed like a great idea.

That turned out to be accurate. The wood gas cars worked very well and wound up being the most successful experiment with alternative fuels to that point in time. They were not only popular in America but could be found in every part of Europe as well. Thousands of refueling stations were established so drivers of these vehicles could purchase and use additional firewood. It was a complete alternative fuel distribution system, and one that was adeptly managed for the benefit of commuters.

After the war, as oil and gas again became more available to civilians and were more convenient to use, the wood gas cars faded into obscurity. They were all but forgotten until recently, when interest was reawakened by modern environmental concerns and rising oil prices. Now, many people are viewing this alternative fuel of the past as a viable energy source for the future.

Hydrogen

One of the most talked-about alternative fuels for motor vehicles is hydrogen. Major car manufacturers are developing cars powered by fuel cells, with early models commercially available by 2013. There is even a World Hydrogen Energy Conference held

biannually, which focuses on uses for hydrogen energy that include powering vehicles.

Fuel cells for cars are used in stacks (multiple fuel cells for each vehicle). This is so that their overall energy production will be sufficient to power the vehicle. The fuel cells use catalysts to convert hydrogen gas into electrons that are negatively charged and ions that are positively charged. The flow of the electrons is employed as electricity to power the car. Meanwhile, the ions (H^+) harmlessly combine with oxygen (O_2) to produce water (H_2O). This enables the car to get the electrical energy it needs, and the sole by-product of the process is water. There are none of the greenhouse gases and other pollutants associated with fossil fuels. Naturally, this makes vehicles powered by hydrogen fuel cells very attractive to environmentally conscious consumers. It is also a major reason why hydrogen is likely to be at the forefront of alternative energy sources for decades to come.

One of the challenges to mass-producing fuel cell vehicles (FCVs) so far has been storing the hydrogen. To this point, the primary method has involved keeping it in high-pressure tanks at 5,000 to 10,000 PSI (pounds of pressure per square inch). The tanks are expensive and heavy. Automotive companies are working to reduce the size and weight to make the tanks more viable for regular use.

A different storage possibility is being explored: condensing the space needed for the hydrogen by keeping it in its more dense liquid form. Of course, doing so requires additional energy expenditure, providing another cost issue to be addressed.

Aside from storage, a key question with hydrogen is its source. If it is taken from methane, coal, or gas, the production process will create pollutants and compromise the environmental goals of hydrogen fuel advocates. Unfortunately, fossil fuels are the primary source used in the \$100 billion industry of hydrogen production, most of which is targeted to industrial use.

However, there are more environmentally friendly ways to secure large amounts of hydrogen. One important method is called fermentative hydrogen production. It uses green algae or cyanobacteria, depending on the version of the process. These tiny life forms feed on carbon-based organic substrate and exhale a combination of hydrogen and carbon dioxide. The carbon dioxide is separated out, leaving the hydrogen available as an

alternative fuel for human uses like powering cars. This is a process that routinely occurs in nature, and it is being repeated in labs as consumer demands for hydrogen energy grow.

Air

As remarkable as it sounds, using air to power vehicles is a viable option. In fact, it has been done on a limited basis for years. The process is a simple one: an air compressor takes in air and compresses it. Next, it is transferred to a vehicle's compressed air tank. This can be a lengthy process that might take hours for a typical car. Once done, the car sends the compressed air into the engine as needed. There, as the air again expands, it releases energy that powers the car. There are no by-products from the process, and thus there is no pollution. Correspondingly, the usage of compressed air does not contribute to global warming or other environmental problems. Additionally, air is free and the compression process is inexpensive. Drivers who use it will be insulated from the rising prices of fossil fuels.

If air cars become prevalent, service stations will undoubtedly maintain supplies of precompressed air, making the transfer process much faster. With the right equipment, the stations will be able to provide this alternative energy source to travelers with air cars on a regular basis.

Electric Car Power Sources

Electric cars are free of harmful emissions, giving them an environmental advantage. They also run smoothly and quietly. For these reasons, using electricity to power vehicles is a great option. The overall environmental impact they have depends on the original source of their electricity.

Solar and wind. Both wind and solar power can be used to produce electricity, and that electricity is then distributed as an energy source for a variety of needs, including powering vehicles. This makes it an indirect alternative energy source for transportation, but still a valuable one. Because they provide cheap and renewable power for electric cars, wind and solar power have gained value as alternative energy sources.

Solar energy comes from the sun. When companies and individuals want to collect that energy in the form of electricity, they set out an array of photovoltaic panels. "Photo" refers to light (in this case,

sunlight) and "voltaic" refers to the production of energy, specifically, electricity. They are also called solar panels. The panels convert the sun's light energy into electricity with silicon semiconductors. The process frees electrons, which are redirected as a current. The current, in turn, can be used to power electric cars.

When owners of solar-powered cars want to ensure that their electricity source is clean solar power, they have two options. The first is to install their own solar panels on their property and collect the electricity produced for use in their vehicle. The second is to buy electricity from a supplier who gets it from their own array of solar panels. Either way, it is an effective means to power a car without producing any of the harmful emissions associated with fossil fuels.

In the case of wind power, it is unlikely to be produced in quantity at a family home, short of living

Salicornia growing near Southampton in the United Kingdom. Salicornia fields can yield up to 250 gallons of fuel per hectare, making the plant one of the most promising biofuel feedstocks.

on an extremely windy mountainside. However, owners of electric cars can still source their electricity to wind by purchasing it from a major producer. There are power companies that make their records available, showing how much they use alternative energy sources, including wind. That information can be obtained by simply calling local power companies and asking for it.

Wind power is typically produced en masse, with hundreds of wind turbines composing what is called a wind farm. Each of those wind farms connects to the local power transmission network, allowing the kinetic energy of wind-powered turbines to be converted to electricity for everyday use. Like solar power, wind power is a nonpolluting process with no dependence on fossil fuels. When this energy is used to power electric cars, it further contributes to the reduction of greenhouse gas emissions.

Wind farms can be on land or offshore, though cost considerations for ocean-based wind farms can be prohibitive. Wind is classified as a renewable power source, and the farms can be placed in areas unsuitable for agriculture, circumventing “food versus fuel” debates.

As a form of purely mechanical power, wind has been used for thousands of years. On a small scale, it can be traced back to ancient Greece. On a large scale, it has been employed through windmills for at least 11 centuries. Windmills famously use this mechanical power to grind flour and to operate pumps for agricultural purposes.

The first known instance of using wind to generate electricity was in 1887, when a professor named James Blyth was able to use wind turbines to power his lights at home. Other inventors quickly followed suit. Included among them was Poul la Cour, a Danish scientist who used electricity from wind energy to power electrolysis. The electrolysis separated water into oxygen and hydrogen. Since hydrogen is another sought-after alternative energy source used to fuel cars, Poul la Cour can be viewed as one of the premier alternative fuel pioneers.

Water. Sourcing power for electric cars from water is another viable option. Water, like wind, offers natural kinetic energy by its motion from one place to another. That motion—again, like wind—represents a renewable energy source, and a clean one free of polluting by-products.

In the 19th century, water started to be used as the energy source for hydroelectric plants. Typically associated with dams on rivers, these plants were also put in other areas with high volumes of water in motion. A famous example is close to Niagara Falls on the U.S.–Canada border.

Currently, over 3,400 terawatt hours of hydroelectricity are generated each year worldwide, making it the most widely used form of alternative energy on Earth. When electric car owners source the power they use to water, they know that the production process is free of pollutants.

Looking Forward

Internal combustion engines that use gasoline are still the standard. Yet, with 1.7 billion cars projected to be on the road by 2035, the emissions from those cars will become of progressively greater concern. The 21st century to date has been defined by increasing environmental awareness, as consumers become better informed about the causes of global warming, acid rain, smog, and other types of environmental damage that harm human health. While efforts to reduce personal energy use will continue, demands for energy from individuals and industry are likely to increase over the ensuing decades.

One reason for that increase by individuals is that new innovations are invented every year. Drivers want every new convenience and gadget, from improved air conditioning and sound systems to customizable in-vehicle computers. Many also want larger vehicles for the sake of comfort and safety. All of these factors together result in higher energy demands for each vehicle.

Industries continue to produce new products, requiring massive amounts of energy and fuel on a global scale to transport larger amounts of raw materials to factories, to manufacture products, and to get finished goods to markets.

These needs will grow further as the world population increases. As of 2011, it was already at 6.974 billion people worldwide. According to United Nations projections, it will be approximately 9.1 billion by 2050. That increase of 2 billion people will mean more individuals driving on the roads and more vehicles in commercial use to bring them goods and services. If all of that energy use continues to center primarily on the burning of fossil fuels, multiple current problems will be accentuated.

One problem is the reliance of Western countries on the Middle East for fossil fuels. This reliance means that the energy needs of the United States and other countries are continually in jeopardy. This jeopardy arises from the fact that instability in the Middle East can compromise fossil fuel supplies at any time. Prices can also spike at any time, resulting in added expense and potential shortages.

Another problem will be an intensifying of the greenhouse effect, as greater amounts of carbon dioxide are emitted in the exhaust of vehicles. This corresponds to rising global temperatures, which adversely affect farmable land and cause sea levels to rise. Global warming has also been implicated in the melting of glaciers and atmospheric disturbances caused by higher ocean temperatures. Those disturbances may adversely affect weather conditions, though a scientific consensus on that is still pending.

An additional environmental effect of unabated fossil fuel use in vehicles will be decreased air quality. Cities like Los Angeles that have many cars and trucks on the roads deal with problems like smog, which manifests as a toxic brown cloud over what should be a pristine coastline. Los Angeles has even had to issue alerts to residents about particularly unhealthy ozone levels, in order to warn them about being outdoors on days of heavy smog. This has been viewed by many as an indicator that air pollution has reached a crisis level.

Naturally, people across the country are concerned about these effects, knowing that they can be visited upon even rural areas in time as traffic increases. After all, as populations grow, urban centers expand, bringing more roads and cars. Thus, there is an eagerness to do something about the problem of polluting emissions from fossil fuel-based vehicles. That eagerness will continue to center on the development and use of alternative fuels. Key among alternative energy sources for transportation will be those discussed above: biodiesel, ammonia, wood gas, hydrogen, solar, wind, and water.

For alternative fuels to be accepted, their environmental benefits will need to be more widely publicized. The more consumers are aware of how alternative energy sources can reduce harmful emissions, the better. Surveys show that most people care about protecting air and water from pollution but

need more information on clean alternative energy sources. Specifically, they need to know how these energy sources work and how they can be used to power vehicles. Environmental organizations and governments are working to provide greater dissemination of that information. Widespread events like Earth Day present a venue to educate the public about these issues. The U.S. Environmental Protection Agency (EPA) also makes available detailed information via its Web site.

Successful acceptance of alternative fuels will also require cost-effectiveness. Consumers want to feel confident that their energy costs will stay the same or decrease as they shift toward alternative sources. Even the most environmentally conscious consumer hesitates if cost is a significant issue, so bringing down costs is expected to have a major effect.

One way to pursue that cost-effectiveness is by using materials and processes that would otherwise go to waste. Used vegetable oil, discussed above, is one good example. When fast food restaurants soak the foods they serve in oil by deep frying, "waste oil" is a by-product. In the past, that excess vegetable oil was disposed of, wasting a potential resource. Millions of gallons would be wasted each year. Thanks to entrepreneurial resourcefulness and growing consumer needs, that by-product is now being constructively used as an energy source.

Salicornia, also discussed above, provides another emerging approach to the development of alternative fuels for vehicles. By using land that other crops cannot prosper on, it circumvents the food versus fuel debate that has hobbled ethanol production in some areas. At the same time, it serves as a rich resource for plant-based oils that can power cars without harmful emissions.

As consumer demand for these alternative fuel sources grows, they will be progressively more attractive to investors. In turn, the capital supplied by these investors will spur new ways to maximize the efficiency of alternative energy production. Costs will come down, and distribution will correspondingly expand. With all these factors in play, the future for alternative fuels looks bright. In time, clean energy for motor vehicles will no longer merely be an alternative: instead, it will be the new standard.

Alternative Motor Fuels Act of 1988

The Alternative Motor Fuels Act of 1988 (Public Law 100-494), commonly designated as AMFA, was designed to clean up the environment and reduce American dependence on foreign oil by rewarding automobile manufacturers who produced vehicles that could run on alternative fuels, such as methanol, ethanol, and natural gas. The bill also included an \$18 million appropriation for the Department of Energy (DOE) to set up commercial demonstrations of vehicles that operated on alternative fuels. Other stipulations involved a mandated DOE study of methanol production plants and a mandated Department of Transportation (DOT)/Environmental Protection Agency (EPA) study of environmental impacts of alternative fuels. The bill also created the Interagency

Commission on Alternative Motor Fuels to coordinate alternative fuels policies and studies and established the U.S. Alternative Fuels Council, an investigatory group comprising four members of Congress and 16 individuals chosen by the inter-agency commission. Both the commission and the council were terminated in 1992 upon final submission of their reports.

Other provisions of the bill paved the way for the creation of the Alternative Fuels and Advanced Vehicles Data Center, which was established in 1991 under the auspices of the Department of Energy's National Renewable Energy Laboratory. Subsequent analysis of the impact of AMFA has produced mixed results; most American cars continue to run on gasoline rather than on alternative fuels, and the dependence on foreign oil continues.

Background

The push for alternative fuels accelerated in the 1980s as the environmental movement gained momentum in conjunction with the increased push to reduce dependence on foreign oil. The most highly touted form of alternative fuel was methanol, which was made from natural gas. At the time, the United States was able to fulfill 95 percent of domestic requirements for natural gas, and the remaining 5 percent was imported from Canada rather than the Middle East or Eastern Europe. In 1987, both Ford and General Motors introduced cars that ran on methanol, ethanol, gasoline, or some combination of the three within a single tank.

As vice president, George H. W. Bush chaired a White House task force that paved the way for the passage of the Alternative Motor Fuels Act of 1988. The legislation (S. 1518) was introduced by Senator Jay Rockefeller (D-WV), who had been working on passage of an alternative fuels bill since 1985. By December 1987, the House of Representatives was leaning toward mandating the use of 10 percent ethanol in all motor fuels.

As an economic incentive, both the House and the Senate were willing to grant mileage credit to any manufacturer who produced vehicles capable of running on alternative fuels. A conference committee was charged with working out the difference between S. 1518 and the House version (H.R. 8399). After five months of negotiation, the conference committee finally agreed on an alternative fuels bill.

President Ronald Reagan signed the Alternative Motor Fuels Act of 1988 into law on October 14, 1988. The final version granted manufacturers who produced vehicles operating on alternative fuels or those who manufactured vehicles that could run on either alternative fuel or gasoline credits toward meeting Corporate Average Fuel Economy (CAFE) ratings beginning in 1993.

Impacts

As congressional support mounted for passage of the act, public opposition consisted of an unusual coalition of environmentalists, oil company officials, and concerned citizens. Even those who supported the use of alternative fuels frequently objected to mandating the use of such fuels. The most frequent argument against passage of AMFA was that both the economic and environmental impact of widespread use of alternative fuels was far from certain.

Oil companies were predictably concerned about additional government regulation. American farmers were concerned about the possible impact on farm subsidies if corn surpluses were directed toward ethanol production. Environmentalists and consumer protection advocates argued that inflating the mileage of vehicles operating on methanol would end up allowing other vehicles to become less fuel efficient, resulting in additional environmental damage and higher operating costs for consumers.

In late 1988, following passage of the Alternative Motor Fuels Act, states began working with automobile manufacturers to create environmentally friendly fleets for government use. California had been an innovator in the area of alternative fuels for over a decade and had established its own alternative fuels program in 1977. After passage of AMFA, the California Energy Commission formed a partnership with General Motors to provide the state with 2,220 alternative-fuel demonstration vehicles capable of running a blend of 85 percent ethanol and 15 percent gasoline (E85). At the same time, ethanol pumps were placed in strategic locations in California. The California legislature had already passed legislation promoting the use of alternative fuels in both private and public transportation, encouraging ridesharing, and replacing energy-inefficient school buses with newer, cleaner models.

In March 2002, a joint report submitted to Congress by the Department of Transportation, the Department of Energy, and the Environmental Protection Agency stated that the impact of the Alternative Motor Fuels Act of 1988 had been mixed. While AMFA had indeed increased the availability of alternative fuels and motivated automobile manufacturers to produce more environmentally friendly vehicles, those running on gasoline continued to be the norm. At that time, there were only 5,236 alternative refueling sites, compared to 176,000 gas stations. Furthermore, only 121 alternative refueling sites offered the ideal E85 mix of 85 percent ethanol and 15 percent gasoline. The price of alternative fuel in comparison to gasoline had proved a deterrent, and many vehicle owners continued to use gasoline in cars capable of running either type of fuel.

Incentives included in AMFA were extended in 2004 when Congress enacted the Automotive Fuel Economy Manufacturing Incentives for Alternative Fueled Vehicles Rule. The following year, Congress passed the Renewable Fuels Standard, and the number of ethanol stations began to increase in the United States.

American Association of State Highway Transportation Officials

The American Association of State Highway Transportation Officials (AASHTO) was established in 1984 as a means of fostering the “development, operation, and maintenance of an integrated national transportation system” within the context of the American system of federalism, which shares certain powers between national and state governments.

Headquartered in Washington, D.C., AASHTO comprises representatives of highway and transportation departments from all 50 of the United States and from Washington, D.C., and Puerto Rico. The nonprofit organization is nonpartisan. In addition to providing advice and technical knowledge to its members, AASHTO develops transportation policy and establishes technical standards in transportation.

The group also serves as a link between state departments of transportation and the U.S. Department of Transportation. Designed to represent the interests of the entire transportation sector, AASHTO deals with issues that are of concern within the fields of aviation, highways, public transportation, railways, and waterways. AASHTO electronically publishes the *AASHTO Journal* each Friday and also delivers a free newsletter via e-mail. Additionally, AASHTO publishes *AASHTO Quarterly* (previously known as *American Highway and Transportation Magazine*).

Organization

The heads of all state departments of transportation serve on AASHTO’s board of directors. An executive director works with the 12 elected members of the executive committee to provide leadership to the group. The various committees that carry on the day-to-day activities of AASHTO are made up of volunteers from state transportation departments who are experts in their fields. Their expertise comes into play when carrying out the ongoing work of standing committees, which include aviation, environment, finance and administration, highway traffic safety, highways, performance management, planning, public

transportation, rail transportation, research, and water transportation.

Some standing committees are divided into area-specific subcommittees. The Standing Committee on Finance and Administration, for instance, has eight subcommittees: civil rights, fiscal management and accounting, information systems, internal and external audit, personnel and human resources, TRAC (transportation and civil engineering), transportation communications, and transportation finance policy.

Special committees are created as the need arises. In 2013, for example, special committees included those on intermodal transportation and economic expansion, joint development, transportation security, and emergency management. The work of the census transportation planning products program (CTPP) is also carried out by a committee, which works with states to gather census data that impact the transportation sector.

Programs

Many of AASHTO’s programs are involved with establishing standards, issuing accreditations, and awarding innovation in transportation technologies. The Technology Implementation group, for instance, champions technologies that are deemed to have a major impact on the transportation sector in fields such as construction, design, the environment, maintenance, safety, and traffic. One recent award-winning technology was the Sequential Flashing Warning Lights for Work Zones system that was designed to improve safety in work zones, guiding motorists through merge tapers at a cost of only \$100 to \$110 per unit.

Another award-winning technology involves the use of Environmental Planning GIS Tools, such as mapping technology to analyze the ways in which the environment is affected by transportation activities. Construction analysis software tools (CAST) also won recognition from AASHTO for the technology’s ability to cut down on traffic congestion while maximizing safe mobility at construction sites.

Outreach

Outreach is a major element in the work carried out by AASHTO, which works with teachers in the fields of science, technology, engineering, and math (STEM) to promote interest in pursuing

careers in transportation and civil engineering. At the elementary level, the Roads into Development in Elementary Students (RIDES) program is a joint project carried out by AASHTO and the Mississippi Department of Transportation. Geared for K–8 students, activities are designed to encourage interest in science, technology, engineering, and math in age-appropriate ways.

In addition to the work done by the organization, members from individual state departments of transportation work with local school systems to develop STEM curricula. Students working on AASHTO modules become engaged in solving real-life transportation problems while carrying out such activities as designing cities and building bridges.

At the elementary level, the Roads Into Development in Elementary Students (RIDES) program is a joint project carried out by AASHTO and the Mississippi Department of Transportation. Geared for K–8 students, activities are designed to encourage interest in science, technology, engineering, and math in age-appropriate ways.

Pool-Funded Projects

AASHTO is also involved in a number of projects in which interested parties from federal, state, and regional agencies work with academic institutions and the private sector to fund and conduct research in particular areas that affect transportation in the United States.

Pool-funded programs include AASHTO Innovative Highway Technologies (LEAD States Program), AASHTO Product Evaluation Listing (APEL), AASHTO Technology Implementation Group, the Climate Change Technical Assistance Program, Joint Development Software Products (AASHTOWare), the Multi-State Technical Assistance Program (MTAP), the National Transportation Product Evaluation Program (NTPEP), Radio Frequency Coordination Procedures and Fee Schedule 511 Implementation, SHRP Product Implementation, and the Snow and Ice Cooperative Program (SICOP). Involvement in such groups occurs according to the discretion of individual state departments of transportation.

Work accomplished by these projects has major implications for the transportation sector, affecting such areas as policy formation, program planning, and budgeting. For instance, the Transportation

and Climate Change Resource Center provides information and services and serves as a resource center for state transportation departments dealing with environmental issues. Policy recommendations are developed by the Climate Change Steering Committee, which works with the Climate Change Technical Assistance Program to help state departments of transportation carry out activities intended to mitigate negative impacts of climate change. AASHTOWare uses professionals to create software that meets the needs of its members. Its software assists state departments of transportation to create budgets, design reports, deal with federal agencies, and work with state officials over time.

Through pool funding, AASHTO is also involved with the National Cooperative Highway Research Program, which was established in 1962. This program conducts research in critical areas such as constructing interstate highways, building bridges, making transportation safer, and protecting the environment in the course of carrying out transportation-related activities.

American Public Transportation Association

The American Public Transportation Association (APTA) is a nonprofit advocacy membership organization that promotes policies, programs, and laws supportive of public transportation in North America. Headquartered in Washington, D.C., APTA's vision statement is to "Be the leading force in advancing public transportation." Its mission, the organization states, is to serve and lead its "diverse membership through advocacy, innovation, and information sharing to strengthen and expand public transportation."

History

Founded in 1882, APTA was originally known as the American Street Railway Association, a membership-based organization of 56 transit companies from across the United States. Beginning in the early 1900s and continuing until the 1940s, predecessors of APTA were the only organizations compiling and publishing data on public transportation in the United States. As the sole source of comparative data on transit administrative, performance, and financial operations, APTA's predecessors became crucially important for researchers and practitioners in the early to mid-1900s. The organization saw a series of name changes, including names like the American Transit Association and the American Public Transit Association before settling on the American Public Transportation Association in 2001. Two other organizations merged with predecessors of APTA—the Institute for Rapid Transit in 1974 and the High Speed Ground Transportation Association in 2007. The group is known for its annual *Public Transportation Fact Book*, which it has compiled since 1943.

As the complexity and regulatory oversight of transit operations expanded alongside government funding in the 1960s, APTA and its predecessors assisted individual transit agencies with reporting requirements, grant applications, and operating assistance, and it continues to do so.

Membership

Beginning with 56 member transit agencies in 1882, the APTA in 2012 comprised over 1,500 member

organizations, growing from 1,270 members in 2000, including groups like transit agencies, engineering firms, universities, and state departments of transportation, among others. According to testimony provided to the U.S. House Appropriations Committee in 2000, 90 percent of public transportation users in the United States and Canada are served by agencies that belong to APTA, reflecting the organization's broad membership base.

Advocacy

The APTA seeks to provide a unified voice for transit agencies and public transportation proponents that both educates the general public and lobbies Congress and state and local policy makers on matters relevant to the interests of mass transit. Seeing its primary roles as advocacy, transportation innovation, and information sharing, APTA releases dozens of white papers each year on topics related to transportation (for example, high-speed rail, poverty, aging, and sustainability) and maintains an active media presence for an organization its size.

Between 1997 and 2012, the organization and its employees donated over \$60,000 to various members of Congress (76 percent of the donations were to Democrats, 24 percent to Republicans). More significantly, as of 2012 the organization employed 10 lobbyists, having spent just under \$20 million to influence policies impactful to public transportation.

APTA also maintains a charitable foundation, the American Public Transportation Foundation, which provides and administers 11 scholarships to students and individuals seeking careers in public transportation. Scholarship recipients must be sponsored by a member of the APTA.

Conferences and Meetings

APTA hosts an annual meeting of its members, which it bills as the primary conference for the transit industry as a whole, with speakers, roundtables, and forums on issues of importance to the organization's membership. In addition, APTA hosts smaller workshops and conferences on niche issues affecting public transportation, such as sustainability, disability access, and multimodal operations. Every three years, the APTA hosts the APTA Expo, a trade show for member organizations to showcase technology, products, and services.

Publications

APTA's most widely known publication is the annual *Public Transportation Fact Book*, a resource compiling hundreds of data points for comparison across the industry, which the organization has published since 1943 and does not copyright. The *Fact Book* not only compiles data from individual transit agencies but also sums the data points across metropolitan areas, providing at-a-glance statistics for all forms of public transportation regardless of provider agency in urbanized regions.

In addition to the *Fact Book*, APTA also publishes an online "Buyer's Guide," a biweekly magazine called *Passenger Transport*, white papers on issues of interest to public transportation organizations, and an online resource library for what it calls "Hot Topics" in public transportation.

Governance

The most senior position at APTA is the president and chief executive officer (CEO), followed by seven vice presidents overseeing specific areas of the organization's administration. The president/CEO is accountable to APTA's board of directors, which is chosen through both elections of the membership and appointments by specific APTA members. There are 104 members of the board of directors. Because the board's size prevents frequent meetings, APTA also utilizes an 18-member executive committee, also elected by the APTA members, which is authorized to act on behalf of the board of directors.

APTA also convenes dozens of committees and task forces that address specific areas of importance to member organizations.

Americans with Disabilities Act of 1990

Passed by the U.S. Congress in 1990 to address the long-term restrictions on the civil rights of Americans with disabilities, the Americans with Disabilities Act (ADA) has affected many aspects of the nation's commercial, community, and public interactions, including those dealing with transportation. Like the Civil Rights Act of 1964, which prohibited discrimination based on national origin, race, religion, sex, or other characteristics, the ADA offers legal protections to disabled Americans. As the ADA expanded conceptions of "disability" to include any physical or mental impairment that limits major life activities in a substantial way, the act greatly expanded how those involved with transportation serve those with disabilities. Public transportation, whether provided by commercial entities or government agencies, must comply with regulations set forth to assure compliance with the ADA. Failure to do so opens transportation providers up to charges of discrimination.

Background

Though the civil rights of individuals were in theory always protected by the U.S. Constitution, it was not until the civil rights movement began to achieve victories in the 1950s and 1960s that individuals from certain ethnic and racial groups and members of certain religions began to have recourse to overt discrimination. During the 1970s, the civil rights of women increasingly began to be examined and protected, as legislation was passed that was intended to prevent discrimination based upon sex. In keeping with this view, the rights of the disabled to be able to access education and other training were progressively expanded. As a result of this examination, in 1975 Congress passed the Education for All Handicapped Children Act (EAHCA), which sought to increase access to public education for children with disabilities. EAHCA, later

reauthorized as the Individuals with Disabilities Education Act (IDEA), only applied to those school districts and government agencies that accept federal funding, but it does require that children with disabilities be provided educational and other services to best meet their needs. This legislation, in conjunction with the Rehabilitation Act of 1973, which mandated that reasonable accommodations be made for those with disabilities by employers, schools, and various others, greatly expanded the civil rights of the disabled.

Throughout the 1980s, the increasing visibility of the disabled in educational and other settings increased expectations among their advocates for more and better opportunities for this group. To that end, calls grew for legislation that would protect the rights of individuals with disabilities in a manner that would better ensure their rights to participate in society. Sponsors of the ADA forged a variety of alliances over the 1980s as they grew closer to their goal of achieving global and comprehensive protection for those with disabilities. With the passage of the ADA, a new assortment of civil rights, and a variety of avenues through which to pursue these, was accorded to individuals with disabilities. In addition to transportation, the ADA addressed the rights of the disabled with regard to employment, benefits, and services provided by state and federal government agencies, public accommodations, and telecommunications relay services.

Reaction to and Scope of the ADA

Designed to be comprehensive in nature, and passed with broad bipartisan support, the ADA was signed into law by President George H. W. Bush on July 26, 1990. Passing the House of Representatives by a vote of 377–28 and the Senate by 91–6, the ADA had faced significant opposition, including from those who believed its implementation would be too expensive.

Many advocates for business interests, including those in the transportation sector, also opposed the ADA's passage. For example, Greyhound Bus Lines, an intercity carrier of passengers, had suggested during hearings on the act that its passage would cause the cancellation of multiple routes, denying many urban and rural communities their most cost-efficient link to travel to other areas. Small business owners in particular felt that the provisions of the ADA would negatively affect their profitability,

especially in light of economic problems already facing the nation. Despite these criticisms, supporters of the ADA emphasized that the legislation would make it easier for businesses and society to access the critical talent pool that the disabled represented. By forcing the United States to become more inclusive, it was argued, a host of employment opportunities would be opened for individuals with disabilities that would permit many more to be self-sufficient and independent.

The ADA provides wide-ranging civil rights protections to individuals with disabilities, prohibiting discrimination based on physical or mental impairments that would otherwise substantially limit major life activities. Determinations regarding whether a specific condition is considered a disability are made on an individual basis.

Comprising five titles, the ADA deals with employment, public entities (including transportation), public accommodations (including commercial buildings), and telecommunications, and also contains miscellaneous provisions regarding the act's implementation and interaction with other legislation. With regard to employment, as covered by Title I of the act, the ADA covers employment agencies, labor organizations, or other employers who have 15 or more workers. The ADA requires employers and other entities to make reasonable accommodations for the disabled and prevents the use of medical examinations unless these are used for all applicants and treated in a confidential manner. Title III of the ADA, covering public accommodations and commercial facilities, requires business owners, operators of hotels and restaurants, recreation providers, and others to ensure that all new construction, alterations, or remodeling efforts remove barriers to the disabled.

The costs of modifications are to be balanced against the potential hindrance to the disabled, thereby requiring larger concerns to spend more than small businesses. Telecommunications companies, governed by Title IV of the ADA, must take steps to ensure that their products and services are available to the disabled, which sometimes requires the provision of equivalent services for those who are deaf, hard of hearing, or who struggle with speech impairments. Title V deals with miscellaneous provisions of the act, and makes clear that nothing in the ADA overrules provisions in the Rehabilitation Act of 1973 or IDEA.

The ADA and Transportation

In addition to prohibiting discrimination against individuals with disabilities by school districts, municipalities, counties, and state agencies, Title II of the ADA requires public transportation to be accessible to the disabled. Public transportation covers a wide variety of services, including city bus lines and public rail transit, such as subways, light rail, commuter lines, and Amtrak. While Title II applies only to public entities, private carriers, such as airlines and intercity bus carriers, are also covered through Title III. The ADA requires public and private carriers to remanufacture buses, trains, and other vehicles in a way that will make these accessible, and to purchase only new stock that complies with the act and the need for this stock to be accessible. Public authorities must also provide paratransit, a service for individuals unable to use regular transit as a result of mental or physical disabilities. Paratransit provides the disabled with door-to-door service, whereby they are picked up at their homes and dropped off at their specific destinations. The ADA prohibits discrimination against disabled persons and mandates that common carriers make accommodations that permit them to serve such individuals.

At the time of the ADA's passage, the overall labor force participation rate was 78 percent, while that of the disabled labor force was only about 33 percent. Part of this disparity was believed to be caused by the paucity of options available to individuals with disabilities for access to transportation that would permit them to travel to job opportunities. The charge for transportation agencies and other providers of public travel options to remove barriers to people with disabilities was often linked to the need for these individuals to go to work and other places that would enable them to better their life options. Although there was a certain amount of initial resistance to the ADA by transportation carriers, the need for the disabled to travel to and from work ultimately proved persuasive and compelling.

Traditionally, analyses of providing transportation services to the disabled focused upon the incremental costs of accessible options. In 1989, the Urban Mass Transit Administration (UMTA), now the Federal Transit Administration (FTA), examined the costs of compliance with the accessibility rules contained in the ADA. At that time, the FTA estimated the costs of compliance with

These Metrolink transit, bus, and Amtrak ticket vending machines in Santa Clarita, California, are two different heights because the machine at right is at an Americans with Disabilities Act–compliant height accessible to people using wheelchairs.

the ADA's requirements to range from \$850 million to \$1.3 billion annually, which was a sum greater than the \$8.8 to \$13.6 billion estimated by the Congressional Budget Office as needed for conformity with these requirements over a 30-year period. The costs estimated by the FTA totaled approximately 5 percent of annual transit budgets, which was the basis of the industry's resistance to the ADA. Rather than focusing on individuals with disabilities as customers with special needs, the disabled were marginalized as a "cost category." As long as the focus of transit professionals centered on costs, especially vis-à-vis other passengers, resistance to the ADA persisted.

Over the past years, however, changes in how transit agencies operate have made it easier for accommodations to be made that directly benefit the disabled. Since 1980, the number of transit trips taken annually has remained fairly stable each year, with approximately 8 billion passengers annually making use of such services. In constant dollars, the national transit budget has also remained fairly

stable, although these numbers have increased slightly since 2009. Despite this apparent stability, a great deal of change has taken place. The proportion of transit miles traveled on commuter rail, light rail, and rapid rail has grown substantially, surpassing miles traveled on transit buses. Indeed, transit bus services and passengers have declined as lower income families became more likely to own one or more automobiles. As new railcars and buses have been purchased, transit authorities have ensured that these comply with the ADA. Litigation has also made clear that courts interpret the ADA as being charged with making existing transit opportunities available to all riders, not mandating the requirement of new transit services. Despite this, many transit agencies have elected to provide paratransit as a lower cost alternative to making the modifications necessary to their existing stock.

ADA Standards for Accessible Design

In 2010, the U.S. Department of Justice promulgated new ADA Standards for Accessible Design, replacing those first released shortly after the act was passed in 1990. The ADA Standards for Accessible Design affect more than 80,000 local, state, and federal governmental agencies and facilities as well as over 7 million privately owned businesses. The more than 54 million Americans with disabilities will benefit from these standards in that new construction, or modifications to existing construction, will have to comply with the standards, which in turn will provide a variety of new opportunities to those whose movements were impeded by barriers to their mobility. The U.S. Departments of Justice and Transportation are primarily charged with implementation of the ADA Standards for Accessible Design, although a variety of federal agencies have some responsibility for their enforcement.

The new ADA Standards for Accessible Design, which took effect in 2012, affect transportation in a variety of ways. All airport terminals, train stations, or other transit facilities must contain elevators when alterations are made to existing buildings or when new structures are erected. Certain minimum widths are established by the ADA Standards for Accessible Design for doorways, corridors, and other passages so that wheelchairs and other devices may be used by the disabled. The responsibility for demonstrating that an equivalent facilitation for the disabled, in the event of a challenge, rests with

the transit authority, making it necessary for most building and remodeling projects to include input from advocacy groups for the disabled from early stages of new projects. Criteria are set forth within the standards that control the construction, design, inspection, installation, maintenance, operation, repair, and testing of lifts used to transport the disabled.

Alterations or construction affecting the functioning of facilities must consider more than just accessibility for individuals with disabilities. Services and amenities in the area, such as drinking fountains, restrooms, telephones, and the like must also be usable by individuals with disabilities unless such modifications are cost prohibitive. At least one accessible route throughout airports, rail terminals, and other transit facilities must be provided so that access is available to disabled individuals from handicapped parking spaces and loading zones.

Remedies Pursuant to the ADA

The ADA provides individuals with disabilities whose civil rights have been violated with access to a variety of remedies. The ADA permits private parties to receive only injunctive relief, such as court orders requiring transportation authorities to provide remediation to address accessibility deficiencies, as well as attorney's fees. Unless applicable state law provides for monetary damages, the disabled may not obtain direct financial benefits for pursuing violations of the ADA. This being the case, significant changes have taken place regarding impediments to transportation as a result of private actions. For example, online travel marketers were forced to modify booking practices on their Web sites to reduce the efforts required by customers with disabilities to research accessible hotel rooms. Additionally, cruise ships flying the flags of foreign nations were determined to be under the purview of the ADA as the result of their having offices in the United States and a clientele that was predominantly American. As these issues have been decided, many transportation agencies and companies have proactively engaged in changes that make their services more accessible to individuals with disabilities.

Automated Guideway Transit

An automated guideway transit (AGT) system, also known as a people mover, is a fully automated transportation system in which driverless vehicles are conveyed along a grade-separated track. Grade separation means that the guideway is at a different

height than other surface transportation so as not to disrupt traffic flow at points where the automated and nonautomated vehicle routes would otherwise intersect.

The term *people mover* originated in the 1960s and is most often used to describe AGT systems that serve relatively small physical areas, such as airports, downtown districts, or theme parks. Originally the term was used to describe two separate systems: Westinghouse Electric Corporation's Skybus, which was prototyped but never developed as an elevated alternative to streetcars in Pittsburgh, Pennsylvania, and the Goodyear Tire and Rubber Company-sponsored PeopleMover, which opened as a Disneyland attraction in 1967. The latter moniker gained popularity and today is used generically to refer to AGT systems as diverse as moving walkways like those found in many airports to magnetic levitation vehicles like Shanghai's airport-metropolitan interchange trains.

AGT systems provide a cost-effective transit solution for delivering high levels of passenger service quality, scheduling reliability, and travel safety. They are used widely at airports, recreational parks, and central business districts, and are increasingly being applied on a larger scale in municipal settings, such as the Metromover serving downtown Miami, Florida, and the SkyTrain linking downtown Vancouver, Canada, with the greater metropolitan area.

Evolution of AGT

AGT was originally conceived as a means of providing mass transit services to accommodate rider loads exceeding those that could be served by existing buses or trams. While buses and trams offered an easy public transit solution for cities and suburbs suffering from traffic congestion, they did not have sufficient capacity or speed—due to frequent stops along a route—to make them an attractive alternative to transport by one's personal vehicle. While offering greater capacity and speed, subway systems generally were too costly to install in smaller cities and outlying areas. AGT offered a solution to bridge the transit gaps.

In traditional subway systems, the bulk of the cost is due to a need for large vehicle size and correspondingly large tunnels, rails, stations, and common system infrastructure. Part of the reason why large vehicle size is needed is the importance

A small monorail track above a water feature at Disneyland in California in February 2010. Theme parks were early adopters of automated guideway transit systems in the 1970s.

of headway, which is the safety distance required between vehicles traveling with limited sightlines through tunnels. Large vehicles under such conditions require a significant headway distance. Automated transit offered an opportunity to reduce headway requirements greatly and thus the size of vehicles and the necessary supporting infrastructure. With AGT, everything from track supports to station size could be reduced.

Smaller vehicles were lighter as well, which opened the door to a variety of suspension methods, from traditional steel wheels to rubber tires, air cushioning, and magnetic levitation. Automated steering systems still had to contend with issues of turning and rights of way without a person at the helm. For smaller systems, the simplest solution was to use a rigid guideway, such as a single light rail embedded in the ground or wall with an attached wheel pressed against it to steer—or guide—the unmanned vehicle along its set path. Some modern systems have eliminated the rail altogether,

replacing it with a virtual one that is read by sensors on the vehicle without the need to have an actual rail or mechanical connection.

AGT systems became a major area of U.S. Department of Transportation research in the late 1960s. By the late 1970s, Boeing and a number of other U.S. aerospace companies had entered the AGT market, followed in the 1980s by Ford, General Motors, and other automakers. At that time, development in the area of AGT began to ignite around the world. However, the market for small AGT systems for mass transit did not. Larger automated guideway systems were easier to integrate into existing mass transit structures, so they found a place in many overworked or underserved subway systems as a way to help support growing capacity and provide services to outlying areas. These types of larger AGT systems have since become a common fixture as part of many municipal mass transit systems.

Smaller scale people movers nevertheless found their own market niche, primarily in airports. One of the first AGT systems to be integrated at an airport was a monorail-style people mover installed at Tampa International Airport in Florida in 1971. The system included one- and two-car pod-like vehicles, serviced by two tracks, that shuttled passengers between terminals.

The Airtrans system installed at the Dallas/Fort Worth International Airport (Texas) in 1975 expanded the concept to include movement of people, baggage, mail, supplies, etc., between terminals and to and from remote operations centers and parking areas. The Airtrans system transported some 5 million people within its first year. Similar systems soon began to be installed at other airports around the world, and today they are ubiquitous at larger airports across Europe, Asia, Africa, and North America.

The theme park industry was also quick to realize the potential cost, infrastructure, and service benefits of AGT systems. The Walt Disney World Monorail System opened in October of 1971 to service the park's Transportation and Ticket Center, Magic Kingdom amusements, and Magic Kingdom Resorts. Throughout the years, the system has been expanded to include Epcot and other attractions and upgraded to enhance comfort, capacity, and control. The Walt Disney World Monorail System emerged early as a prime

model for the effective implementation of AGT systems at entertainment parks and continues to be a leader in that regard for park enterprises all over the world.

Advantages of People Movers

AGT systems can be operated at very short headways—typically 60 seconds or less—even in peak hours and can travel at high speeds as permitted by the track design and the distance between stations. The same service frequency of AGT systems can be maintained during off-peak hours as well without incurring significant operating costs thanks to the driverless automated guidance feature. The reduction in passenger waiting time during off-peak hours helps ensure quality of transit service.

In terms of both cost and capacity, most larger AGT systems fall between light rail systems and rapid rail transit systems. Smaller AGT systems like those found in airports or theme parks have average capital costs and capacities below that of light rail systems. However, AGT systems tend to have superior service quality, reliability, and safety compared with standard light rail and rapid rail transit systems. In terms of service quality, the precise control of speed, acceleration, and deceleration that AGT people movers provide deliver a smooth and efficient experience for riders.

The reliability of AGT systems at both peak and nonpeak times also adds to their high marks for service level. Consistency is also important on an operational level, as any delay in transportation at an airport, for example, may cause considerable loss to the airlines and to the entire airport enterprise itself, both financially and in terms of goodwill.

Safety is a key concern during the design and operation of any transit system, and even more so in the case of automated systems where there is no operator on board to address emergency situations. With AGT systems, passenger safety is ensured by fail-safe vehicle control systems and the application of advanced technologies for certain systems, such as door operations.

While AGT systems offer a cost-effective means for safe and efficient transport in activity centers such as airports and recreational parks, they also can be used to improve transportation planning, utilization, and public perceptions related to urban

transit services. AGT systems are significantly smaller than rail transit, enabling them to negotiate sharper turns and steeper grades. The smaller and quieter stations needed to support AGT systems can be integrated directly into buildings rather than requiring them to be stand-alone systems. The ability to integrate the stations into existing infrastructure makes AGT services easier to implement for transportation agencies and more attractive to the traveling public, which in turn helps increase ridership and boost financial viability. By connecting periphery areas and services, such as parking, with various parts of the urban center, cities can create a more focused, higher density pedestrian core while reducing downtown vehicle volume and traffic congestion.

The smaller scale and integration opportunities of AGT systems and stations also open opportunities to link real estate and business development processes with mobility systems planning. Enhancements to transportation infrastructure and services tend to be attractive selling points for both residents and businesses, helping feed a cycle in which those offerings lure dollars to the area that can then be used to justify further transit enhancements in a mutually beneficial cycle.

Automated Landing Systems, Airplane

Automated airplane landing systems, or autolands for short, are systems for automating the landing process of an aircraft, reducing the role of the flight crew in that process to one of oversight. Autoland is a subtype of autopilot system, often used in conjunction with an instrument or microwave landing system, and was originally designed to land aircraft in conditions of limited visibility. Today autolands may be used in a variety of visibility and weather conditions, often in conjunction with automated brake systems (which include wheel-based autobrake systems as well as the automated deployment of thrust reversers and spoilers to slow the aircraft's forward motion).

Autoland systems were first implemented in commercial aircraft by British airlines because of the especially poor visibility conditions that prevailed in the industrial cities of the United Kingdom and parts of western Europe, where anticyclonic activity in early winter formed thick fog mixed with particulate pollution from coal-burning plants. The frequency of accidents when pilots attempted to land in these conditions led to the development of a "specialized autopilot" system, based on the recognition that landings are all fundamentally similar.

Early work on the problem led to the groundwork for the crew resource management systems used today, as one pilot would monitor visual cues while the other would fly the plane by instruments. Further work aimed to automate the instrument landing system (ILS, which, like other instrument systems, relies on instrumental readings rather than visual cues). British work on the systems continued for years after, beginning in the 1940s, mostly as part of the government's Blind Landing Experimental Unit (BLEU). The main problem was the unreliability of ILS at altitudes below 200 feet. While this was acceptable at many airports, the particular visibility problems faced at British airports and those in some of the more industrial European cities were especially pronounced at ground level.

Autoland systems were implemented in British Royal Air Force aircraft and experimental BLEU aircraft in the postwar years and were incrementally adopted in commercial aircraft around the

1960s. The first autoland systems used in commercial aircraft were limited in scope compared to the full autoland systems of the military and are sometimes called autoflare systems. They simplified the landing procedure by controlling the flare of the craft (reducing its forward energy) while the pilot controlled the roll and yaw manually. Even this was a significant improvement and greatly reduced the number of landing accidents. Autothrust was soon added. These early commercial versions of autoland were not universally usable, however. They were effective for fog, and for the "London fog" (primarily low-lying coal smog) they had been designed to deal with, but they could operate only in stable conditions without turbulence or strong crosswinds. This situation gradually improved as integration with instrument landing systems and roll and yaw controls was improved.

Modern autoland systems receive signals from a ground-based instrument landing system, which is regularly calibrated according to international standards in order to ensure accuracy. Typically, the aircraft's interaction with the ILS at the destination begins well before the landing procedure, as the autopilot maneuvers the plane into its approach based on the ILS data. Two key elements of the ILS, operating as independent subsystems, are the localizer (LOC), an array of directional antennae pairs that transmit narrow beams to either side of the runway's center, making its location clear; and the glide slope (GS), an antenna array that provides vertical guidance data.

After the autopilot maneuvers the aircraft into position to land, the autoland system adjusts the throttle to maintain a correct approach speed and maneuvers the aircraft through the landing procedure and final descent. This involves following the glide path (the path dictated by the glide slope) and lining up with the coordinates given by the localizer, while descending in altitude at the right speed. This procedure is overseen by the flight crew, who check the autoland's performance against any visual cues that are available. Even in poor visibility conditions, the approach lighting of the runway is often visible and gives information about the aircraft's proximity to its target. At airports without towers, pilot-controlled lighting is used, with the approach lights and edge lights turning on and adjusting their intensity in response to pilot commands issued over radio.

The actions after touchdown are as important as the final descent. Typically, modern autoland systems are integrated with other automated systems for braking. Wheel-based systems increase friction on the wheels to slow their movement, while thrust reversers apply force in the direction opposite to the aircraft's motion to counteract its inertia and decelerate the vehicle. Spoilers, which are deployed automatically, create a turbulent airflow over the wings of the aircraft in order to prevent the lift for which they are otherwise designed.

Autoland systems are not perfect, but when something goes wrong, it is usually because of a failure of equipment at the airport, not on the aircraft. Glide slopes and localizers that have not been properly calibrated or frequently inspected may report incorrect information that can result in a crash when combined with poor visibility in which the flight crew has no visual ground reference.

Regulations require that a pilot be authorized to operate an aircraft with autoland. Categories of pilot authorization align with the three ILS categories (I, II, III) and require a specific number of actual and simulated flight hours during instrument conditions. For instance, federal aviation regulations require that a person applying for Category III pilot authorization already hold a pilot certificate with an instrument rating, as well as the type, category, and class rating for the aircraft for which the authorization is sought. In addition, applicants must have at least 75 hours of instrument flight time (of which no more than 25 or 40 hours may be simulated, depending on whether or not training takes place at an appropriate training center), 250 hours of cross-country flight time as the pilot in command, and 50 hours of night flight time as pilot in command. The ILS categories are based on "decision high" (the minimum height above the touchdown zone at which the landing begins) as well as visibility minimum and runway visual range. Category III is further subdivided into IIIa, IIIb, and IIIc, although IIIc is not an active category since it refers to conditions of zero visibility.

Automated Passenger Counters

Automated transit passenger counters, or APCs, are electronic systems that maintain a count of passengers on board a transit vehicle (such as a bus or train). The Federal Transit Administration (FTA) requires ridership information to be reported to the National Transit Database (NTD) and accepts data from APCs, which it also inspects to ensure correct calibration. Without APCs, transit agencies must use manual schedule checkers, which generate estimated ridership data by manually counting the number of passengers on randomly selected trips and multiplying that figure by the number of trips in a given length of time (typically a month). Though the systems used for manual counts are usually carefully designed in order to minimize the effect of anomalous trips with unusually high or low numbers of passengers, they are nevertheless obviously less accurate than the true ridership counts provided by APCs. Further, APC counts are not distorted by transit agency actions that inadvertently distort manual counts. For instance, if a transit agency cancels an 11:30 bus because it has consistently low ridership, then by definition this will have little effect on the agency's monthly ridership totals; but using the manual method, it will have a significant effect on the count.

Accurate ridership counts are important for a number of reasons. Reporting to the National Transit Database is required as part of a larger group of data transit agencies are required to report to the FTA, including their compliance with the Americans with Disabilities Act and with the Title VI requirement to distribute transit services equitably. The information reported to the National Transit

Database pertains mainly to ridership, financial information, and safety and security (notably reporting the number of accidents and crimes that occur). Reported ridership information includes unlinked passenger trips (UPTs), meaning each trip, defined as a passenger boarding, traveling, and then disembarking, regardless whether they then transfer to another route; total number of trips according to time of day; and total passenger miles, meaning how far passengers travel.

For their own purposes, transit agencies usually track more data than this, including the relative popularity of various routes, seasonal or other time-based factors that impact route popularity (such as the impact of Red Sox home games on Boston's Green Line subway route), the length and frequency of trip delays, the correlation of safety or security incidents to specific routes or times, the correlation between crimes committed on transit vehicles and the crowdedness of those vehicles, and the frequency with which buses or trains are full to capacity and are unable to let all passengers board, requiring some to wait for the next vehicle. But most of this information builds on the accurate ridership count that only APCs can provide.

The complete level of detail provided by APCs has not only made it easier for transit agencies to report their information to the NTD and improved the quality of federal information on transit use, it has also challenged many of the tenets of conventional wisdom that had guided the transportation industry in the past. For instance, it used to be held as true—and many still advocate this view—that increasing fares or reducing services will lead to declines in ridership. The available facts even appear to bear this out sometimes, when the sampling and manual count method is used for estimating ridership. In recent years, for instance, the cities of Sacramento, California; Los Angeles; and Chicago have all cut their services in response to the budget tightening following the 2008 financial crisis, as well as other factors. Opponents of the cuts predicted severe ridership decline.

Severe ridership decline was subsequently reported by Sacramento but not by Los Angeles or Chicago. Sacramento does not use APCs; Los Angeles and Chicago do. While it is not possible to know for certain that Sacramento's ridership figures are inaccurate, the general trend does seem to indicate that using a manual count exaggerates the negative impact of fare increases and service cancellations.

Analysis

The ridership data collected by APCs is analyzed by the transit agencies using specialized geographic information system software like ArcView, which was developed for the transportation industry by the ESRI Corporation. ArcView takes database and spreadsheet data and combines them with geographic and spatial information to create maps that not only go far beyond the old-style schematic maps, by combining route and stop information with real-world geographic data and scale, but also incorporate ridership information, such as the number of riders who take certain routes at certain times and the relative popularity of different stops. The average load (number of passengers) carried by a bus or train at any given segment of a trip can be displayed. If a given route that has been experiencing overcrowding is only overcrowded for a particular segment of its trip, for instance, and this is shown to be consistently true, that is a problem that can and should be solved differently than if overcrowding is experienced at all stages of the route. Before the use of APCs and GIS software, however, only driver anecdotal data would have revealed this, and given how harried and distracted drivers are during conditions of overcrowding, the accuracy of that data is inconsistent.

The use of APC data with GIS programs can also help in planning potential routes, examining the effects of route cancellations, and evaluating the impact of changes to transportation infrastructure, such as detours or delays caused by construction. The effects of other changes can be explored as well, such as the potential increase in ridership as new residential areas develop or changes in commuting patterns as a business district expands. Attempting to extrapolate information from data is an operation that inherently has a considerable margin of error, especially when there are multiple factors at play (for example, in considering the impact of a new residential area, the transit agency cannot know in advance how heavily residents might depend on public transportation rather than using their own cars, bicycles, or walking). That margin of error becomes unusably large if the available data are not reliable—another argument in favor of APCs.

Automated Road-Pricing and Toll-Collection Systems

Road pricing and toll roads are travel demand measures that involve payment for accessing a designated area or motorway respectively, so that the costs of traffic congestion, which generally reflect a fundamental, usually peak-hour, imbalance between the supply of and the demand for road space, can be spread in accordance with actual road use. Automated (or electronic) road pricing and toll collection systems constitute an increasingly popular alternative to the conventional cash-based and tollbooth-oriented charging operations that have been used to collect transport revenue from motorists all over the world for many years now.

Electronic toll collection (ETC) reflects today's digital era because it uses technology to maximize revenue generation. This means that the toll collection mechanisms become more systematic and logistically reliable, maximizing road pricing's potential as an efficient revenue generator. More importantly, however, ETC operations radically enhance the road user experience in terms of

mobility, safety, reliability, and travel convenience, given that vehicles need not stop to pay the toll. This all-electronic, nonstop, open-road tolling process that replaces stationary payments prevents major highway bottlenecks occurring around toll plazas, which have been associated with other, less advanced methods of toll collection.

ETC systems in general and electronic road pricing (ERP) in particular provide proven congestion charging solutions that have been successfully tested in an applied sense around the globe. One of the reasons for this success, which differentiates these automated systems from less sophisticated ones, is that an intelligent tolling scheme allows the authorities running its operation to determine specific congested points within the designated road charging zone and, if they choose to do so, to fluctuate the rate of the charge according to occurring traffic conditions. Therefore, the charges can increase or decrease according to the specific requirements for road space demand at the exact time a driver is entering the pricing zone. This is a function that could ultimately provide the policy makers with a dynamic charging apparatus that offers, in principle, the potential to make tollway operations more flexible and equitable in real societal terms.

The Need for Automated Road Pricing and Toll Collection Systems

Road traffic congestion is costly not only to the individual but also to the society as a whole. More specifically, traffic congestion is responsible for travel delays and thus the loss of productive time, environmental degradation, excessive fuel misuse, and adverse health consequences for the people who have to live in cities subjected to it. A number of studies in the past referring to the particular characteristics of the traffic congestion occurring on toll roads concluded that the heaviest congestion takes place near toll gates, where cars traditionally had to stop in order to pay the charge manually. This means that a significant source of severe traffic congestion can be alleviated by introducing methods of tolling that permit vehicles to continue their course of travel without stopping on toll plazas.

"Intelligent tolling operations" refers to the payment of a fixed or varied charge for accessing a particular section of a road network that is usually

This electronic road pricing (ERP) gantry suspended over a road in Singapore is part of an open-road tolling system. Singapore's congestion-pricing ERP system was the first in the world.

highly congested, and they are organized around the automated identification of the vehicle entering the charging zone and successively (in most automated tolling scenarios, that is) the electronic collection of the fee.

This is being achieved through the wireless communication between an in-vehicle device and the system's toll gate antenna or an ERP gantry. This automated procedure allows the vehicle fleet accessing the charging zone to pass through toll gates without stopping, and thus without slowing down significantly the traffic flow. In some less advanced automated systems, cars have to reduce their speed on toll entries to allow the wireless operations to function properly, but even then this has a minor impact on the overall smoothness of the traffic flow when compared with the effect that the stop-and-pay tolling mechanisms have.

The Benefits of Automated Road Pricing and Toll Collection Systems

Reducing road congestion in areas where non-automated tolling systems could have led to traffic bottlenecks and crafting an unimpeded traffic flow are beneficial in multiple ways. Excessive fuel consumption resulting from vehicles that have to repeatedly stop and then reinitiate their trips at toll stations is eliminated. Emissions are consistently reduced, which aids in preventing global warming. This nonstop operating principle is also effective in diminishing noise levels around toll plazas. A more direct anthropocentric benefit is that drivers' cognitive efforts and stress levels are minimized as the charging process is automatic and drivers do not have to stop or carry money with them.

By charging road space, these advanced systems help regulate and distribute vehicle usage in a way that supports the road network's optimal use principally by encouraging motorists to consider alternative modes of travel. However, ETC systems in general could also direct road users to choose alternative travel routes to their destination to avoid the charge, travel during the off-peak periods, take different lanes in a motorway (e.g., not an express lane), or even adopt car sharing to split the costs of commuting. Electronic tolling has also been an efficient mechanism for keeping traffic speeds within the road system's optimal speed range because of its success in reducing traffic congestion.

Privacy Issues

A major social issue of automated tolling in terms of social implications is privacy. Privacy is regarded as a basic human right that is an intangible cornerstone for the society's well-being. ETC and ERP are both linked with the generation of a significant volume of detailed, aggregate, personal, and potentially dynamic identification data. These data are utilized as objective documentary proof of violations and allow electronically tagged vehicles to be accurately tolled even, in some cases, at a traveling speed of up to 100 kilometers per hour, but there is a less straightforward and potentially obscure dimension to this. The system's facilitators are given the opportunity to conduct real-time or retrospective surveillance of the movement of vehicles and people—something that could be a threat to the autonomy

of the individual and result in the loss of anonymity and possibly the loss of information privacy. Securing privacy in ETC applications therefore should be a fundamental design criterion, a clear statement of an individual's right to voluntary and informed participation in the scheme.

A Look Into the Future

The next generation of tolling systems is going to fully embrace the use of the Global Positioning System (GPS). A GPS-based tolling system could overcome the inflexibility of having physical toll entries by introducing virtual ones. By making automated distance-based tolling totally operational, road access charges will be calculated according to the actual distance covered by motorists within a charging zone and therefore could be entirely associated with usage criteria. This will make ETC systems even more equitable.

Automated Traffic Control Systems

Historically, traffic control for all modes of transportation took a number of forms, all of them relatively informal, to avoid collisions or to ensure that certain vessels or vehicles had the right of way. Even before the Industrial Revolution the growth of population and traffic in cities made traveling in the streets a dangerous proposition. As a result, in

London in 1868 an experiment was performed in which a lantern was used as a signal to let horse-drawn carriages know when to stop and when to go ahead. Initially, the traffic signal was successful. However, early the next year the gas line connected to the lantern ruptured, creating an explosion that killed the policeman operating the signal.

As busy as traffic had seemed with the proliferation of horse carts and carriages, the congestion and danger dramatically increased with the appearance of automobiles. Automobiles not only increased the number of vehicles in the street but, because of their speed and noise, increased the danger to drivers and pedestrians.

By 1912, the idea of using a traffic light to control who would go and who would wait at intersections seemed to be worth revisiting. In that year a traffic signal lamp was installed in Salt Lake City, Utah. Two years later a traffic light was installed in Cleveland, Ohio; the lantern was operated automatically but the controls could be overridden by police at the neighboring station.

The increased number of vehicles and drivers did nothing to increase caution on the part of those who actually drove the new machines. Accidents with horse-drawn vehicles or with other automobiles were all too frequent. The possibilities of a fatal crash with a train were not yet absorbed by drivers. As late as the mid-1920s, in an area as sophisticated as the region around New York City, accidents as the result of automobiles crossing railroad tracks when trains were running were fairly common. By this time, state and local governments as well as the federal government were concerned with rising fatalities and were beginning to take measures to establish traffic control systems that would move increasingly from those operated on the spot by individuals to those operated in an automated fashion.

Definition

Traffic control in one form or another has existed for every mode of transportation, be it horse-drawn wagons, canal boats, river traffic, railroads, or aircraft. While some parts of the traffic control processes have been automated, only in the area of controlling automobile and truck traffic has the process become completely automated. The chief means of exercising this control has been the use of traffic signals, now almost entirely the use of traffic lights

(which now number over 330,000, according to the U.S. Department of Transportation [USDOT]).

With the exception of those small towns that still have only one stop light in the center of town, municipalities have networks of traffic lights that form a traffic control system, and these systems are invariably networked and controlled in an automated fashion. It is these networks (and specifically not traffic signs) that constitute the automated system.

These automated systems are based on two types of traffic light systems. The first comprises lights that change their sequence (green, yellow, red) on a timed basis. The second is the variable light that operates based on information received from sensors. The length of time that the light stays on depends upon how heavy the traffic is. What has become a critical issue is the coordination between lights in the same system and how they operate given how heavy traffic is as well as other factors. In many instances, coordinating the signals among lights in one system has become an important activity in managing highway traffic in municipalities. Thus, automated traffic systems have accomplished a great deal in their primary mission of preventing accidents and saving lives. In other regards, however, it has become necessary to re-examine their use to counter other problems that they have created.

Improvements

While there can be no doubt that traffic lights have saved lives and will continue to do so, there is an adverse effect as well. The traffic control system networks in cities have been, in the past, largely uncoordinated or coordinated only partially. Coupled with the effects of increased numbers of vehicles on the road, the result has been the creation of congestion and traffic jams that leave drivers frustrated and cause delays. More importantly, the delays caused by uncoordinated traffic light networks are responsible for wasted energy and increased pollution from cars idling while their drivers wait for a light to turn green. According to the U.S. Department of Transportation (USDOT), 10 percent of all traffic delays are attributed directly to poorly coordinated traffic signals.

The National Transportation Operations Coalition (NTOC) is an organization composed of private-sector groups from all levels (national, regional, local) with an interest in safety and

effective transportation operations and planning. In 2005, the NTOC gave the nation's traffic control system a rating of D minus.

Despite the current problems, the means to improve this situation do exist, thanks to new technology as well as improved means of studying how traffic flows can be improved. As an example, in 2005, the city of Colorado Springs, Colorado, developed a plan for synchronizing its traffic signals. While there are variations in plans advanced by other cities as well as regions and states, the Colorado Springs document illustrates many of the factors that any government must address in order to improve its traffic flow by making improvements to its traffic control system. One thing to note in this and most other efforts is that the efforts do not include the construction and deployment of more traffic lights but instead improve the effectiveness of the existing system through a detailed study of current operations and the acquisition of advanced hardware and software.

In reviewing the state of the traffic control system in Colorado Springs, the board had to consider several factors in examining how cohort groups (referred to in the report as "platoons") of cars flowed and were affected by stop lights. First among these was to keep in mind the corridor speeds for specific stretches of the road network. If large numbers of cars exceed the speed limit or if they operate at a significantly lower speed than that posted, there will be excessive numbers of cars that must stop. The space between signals is also crucial because if there is a uniform distance (typically in Colorado Springs, at least, about half a mile) between signals, then coordinating lights to keep the flow moving will be easier to accomplish. If there are many lights spaced at variable distances, it will be difficult to effect the coordination of lights.

The road's capacity is another factor. If a road does not have the capacity to handle current traffic loads (unfortunately, a not uncommon occurrence as vehicles are increasing at a greater rate than that at which infrastructure is enhanced), the traffic will tie up. There are some fixes that can be made, but unless the roads can be widened (an unlikely option), these areas with a smaller capacity will continue to cause problems. Variations in traffic at different times of day can inform decisions about the best way to program timing for lights that can also mitigate the problem of congestion at these specific points.

Other factors also must be taken into consideration in the planning process. These can include pedestrian and bicycle traffic and the frequency of left-hand turn lanes and their signals. These lanes and lights, while they make it possible for drivers to make left turns in safety, also tend to cut the amount of time that the green light stays on for through traffic. Two-way traffic requires coordination of lights in two directions, which also complicates the calculations to be made. There is also the timing of the yellow light as a warning to stop (typically five seconds) and then the amount of time in which all lights are red (typically two seconds). While this last is also an important safety consideration, it too reduces the amount of time available for a green light for traffic to drive through. Finally, long-range planning must be conducted as a follow-up to the project. The recommendation is that the traffic control system must be evaluated again within two or three years after the first project. In cases where the route is heavily traveled, it should be reviewed and reimplemented more frequently.

Organizations

The expertise required to effectively coordinate the components of traffic control systems is not usually resident at the local or state level. There are organizations, however, both governmental and nongovernmental, that provide support to agencies seeking to improve their automated traffic control systems.

One of these organizations is the American Association of State Highway and Transportation Officials (AASHTO), which counts every state Department of Transportation (DOT) as a member and provides expertise derived from experience, design committees, and research. It develops standards and provides technical advice and best practices documents to state and local government organizations in transportation matters. It also has a national Committee on Uniform Traffic Control Devices that works on signs, devices, and design practices to be used at railroad-highway crossings. Another resource for state and local governments is the Institute of Transportation Engineers, a private organization that works with the USDOT. It is not only a repository of expertise but also performs outreach in the form of developing standards and publishes the *Traffic Control Devices Handbook*.

In addition to these organizations, there is also assistance from the Federal Highway Administration

(FHWA), one of the 10 administrative offices within the USDOT. The support it provides to improve the operation of automated traffic control systems is wide ranging.

A major area of FHWA assistance is the technical guidance and expertise it provides through the *Manual for Uniform Traffic Control Devices*, a publication that has been issued in one form or another since the late 1920s. The manual, generally referred to as MUTCD, provides guidance for all types of instruments to control traffic.

In addition to the MUTCD, the FHWA provides a wide range of support and expertise. This includes tools and software packages (it should be noted that there is also a healthy private industry that supplies traffic control planning software tools). The most significant of these is the Intelligent Transportation Systems (ITS), which includes communications capabilities data collection and analysis software. It also includes the Adaptive Control System (ACS), which, in its regular and "lite" versions, has been used successfully at several locations. Both the state of Texas and state of Delaware have used ITS successfully. Cities that have used ITS include Syracuse, New York; Seattle, Washington; Salt Lake City, Utah; Denver, Colorado; and St. Augustine, Florida.

All of these cities have had significant problems, but perhaps the city with one of the most notorious traffic problems that was solved using the latest technology in an iterative fashion is Los Angeles, California. In April 2013, the *New York Times* reported that the city had completed its Automated Traffic Surveillance and Control System, which was begun in 1984. The complete traffic control system comprises 4,500 street signals and is the largest and most complex of its kind. Using sensors at many locations, the system (using software specifically developed for this project) receives information that not only coordinates the main flow of traffic from point to point but also takes into consideration schedules for buses and when they get an extra green light.

Unfortunately, it is generally agreed that the improvement in the amount of traffic that passes through with less difficulty will result in even more traffic and probably within the near future.

Automated Traffic Enforcement

Traffic laws regarding speeding and traffic lights are among the most commonly broken. This may be because individuals do not feel it to be morally wrong to speed or run traffic lights. No matter the reason, these laws are often broken, and law enforcement is tasked to do something about it. For this reason, automated traffic enforcement technology is often used to detect both speed limit and traffic light violations. By using these technologies, law enforcement personnel are able to refocus their efforts on other matters. However, these systems are not without their detractors, who raise concerns regarding privacy and civil liberties issues.

Speeding

Police officers may determine the speed of a vehicle through either radar or laser-based systems. Police have been using radar to catch those who violate the speed limit since the 1950s. This method determines the speed of a vehicle via echo location at multiple points over the vehicle's course of travel.

The technology is fairly limited, and many departments have transitioned to laser-based systems.

More technologically advanced police forces use a laser-based system commonly known as LiDAR, which stands for "light detection and ranging." The system is entirely laser based and shares no technology with radar, despite the similarity of the name. A typical LiDAR system determines the speed of a vehicle by firing several hundred beams of infrared light at its target. The beams are then reflected back to the LiDAR gun and timed, thus giving a reading. LiDAR systems may be manned or completely automated. Manned systems typically are operated by officers stationed on the side of the highway. Automated systems are programmed to detect speeding cars and record the times when violators are detected.

Traffic Lights

The basic elements of an automated traffic light monitoring system are as follows: one or more camera, one or more trigger, and a computer. Cameras may be either film based or digital, and the number of cameras may vary based on the standard of evidence required for a traffic ticket by local or state ordinance. Film cameras are more common to older systems, while digital cameras are newer and often capable of recording in a variety of ways.

Automated recording systems for traffic signals may be based on either induction loops or video loops. Induction-loop systems are based on electromagnetic circuits that are embedded in the asphalt beneath the street and connected to stationary cameras. The wire embedded in the asphalt is typically positioned near the stop line. From that position, the wire creates a magnetic field. If the field is disrupted by the metal mass of an automobile, the circuit is broken and cameras are triggered. The computer component is the hub of the automated recording system. The computer maintains and monitors the trigger circuit, monitors traffic signals, stores the images from the cameras, and timestamps those images with the date, time, location of the intersection, speed of the vehicle, and other information useful to law enforcement.

Video-loop systems operate in a manner similar to induction-loop systems, except they operate without the electromagnetic wire; instead, they rely more on digital cameras to determine when a red light has been run. The cameras are programmed

to recognize vehicles moving through the intersection when the light is red. Once recognized, video frames are recorded for the span of the infraction and time stamped. While these more advanced systems possess a variety of advantages over older induction-loop systems, the greatest advantage is that the asphalt does not need to be torn up every time the trigger needs adjustment.

Another major advantage of automated traffic enforcement systems is they defuse emotions surrounding the interaction between law enforcement and citizens. When drivers are pulled over, emotions often run high and dangerous conditions can develop; by eliminating the pull-over situation, citizens and officers are kept out of harm's way. If caught by the automated system, the driver can expect a ticket and a picture of the violation to arrive in the mail within one or two months. Laws vary by state on standards of evidence in this situation. Some states automatically issue the ticket to the car's owner; in these states, the camera simply takes a picture of the license plate. Other states ticket the driver. In these states, an additional camera is in place to capture a picture of the driver. The ticket is still sent to the owner of the car, but if the individual in the image is not the owner, the owner may appeal the ticket.

Controversy and Legislation

While a technology that simply catches and punishes individuals who are breaking the law may not seem controversial, there are some serious privacy concerns associated with automated traffic enforcement devices, especially video-loop technology. Not only do the video cameras capture those who are running red lights, but they also can be used to collect evidence of any crime or activity within the range of the camera. In fact, this is one of many reasons why the American Civil Liberties Union (ACLU) and other organizations oppose this technology.

This process through which cameras are used for investigations for which they were not originally intended is often referred to as "mission creep." The ACLU also argues that the time delay of as long as two months is a violation of citizens' constitutional rights to due process. These delays, it is argued, can inhibit the ability of the accused to appeal the ticket because it may be difficult to remember an event that occurred so long ago. The ACLU further

A red-light camera in use in Chicago, Illinois, in 2010. Automated traffic systems have raised privacy questions and have been banned by voters in numerous U.S. municipalities.

points out that automated systems tend to identify license plates incorrectly, and studies have shown that automated systems may increase incidents of rear-end collisions.

The ACLU is not the only group that has raised issues regarding automated traffic systems. These unpopular systems have been banned by numerous voter referendums and city council motions across the United States. Arguments frequently raised include that the cameras are installed solely for revenue purposes, the cameras are not an effective deterrent, and conflicts of interest are created when private contractors receive commissions based on the number of tickets generated by the system.

Automated Transit Systems

Automated transit systems (ATS) are coordinated transportation systems in which vehicles are operated without a driver. An essential component of driverless systems is a fully protected route of travel. Specifically, the track along which the driverless vehicles move—whether it be at ground level, elevated, or underground—must be kept free of any obstructions, including potential access or crossing by pedestrians, automobiles, other operated vehicles, and even animals. The vehicle is controlled by an automated system, and there is no operator onboard to be able to visualize or observe a potential collision hazard ahead.

ATS vehicles themselves vary greatly based on size, shape, and underlying technology. For example, the ATS vehicles can be propelled by linear or rotary traction electric motors placed on the vehicle itself, by motors or even magnets embedded in the

track system, or by cable pulley. They can ride on steel or urethane wheels, rubber tires, air cushions, or have no ground contact at all, as in the case of magnetic levitation. Depending on their size, speed, and quantity of conjoined cars, the ATS vehicles can carry from several hundred to several thousand passengers in each direction every hour. Capital investment and costs associated with ongoing operations and maintenance vary significantly based on the system's size, location, complexity, level of technology, and carriage requirements.

The concept of automated transit systems began in the 1960s and has evolved over four decades to include more than 100 in-use systems at airports and urban centers in countries around the world. ATS offers advantages in the areas of mass transit service, travel speeds and capacity, and operational costs.

ATS Applications

The most prevalent application of automated transit systems is found in driverless rapid transit (DRT), followed by automated people mover (APM) systems and personal rapid transit (PRT) systems.

Driverless rapid transit systems involve group, rather than personal, rapid transit. The vehicles tend to resemble trains and are designed to carry a large number of riders along a predetermined route. The vehicles stop at multiple stations dispersed throughout the route. DRT is best suited for high-capacity, line-haul applications. The vehicles associated with DRT range from 50 feet to 100 feet (15–23 meters) and can be up to 10 feet (3 meters) wide. Their size makes them too large to maneuver swiftly through intricate systems associated with the people mover applications, especially when the vehicles are typically linked into one "train" by connecting as many as 10 cars together. The vehicles are usually self-propelled by attached motors and ride on steel wheels. The massive driverless vehicles can travel up to 60 miles per hour (100 kilometers per hour) and transport 10,000 to 50,000 passengers in each direction every hour.

Automated people mover systems are similar to DRT systems in that they involve group versus personal rapid transit. Like DRT systems, APM systems carry large numbers of passengers along a pre-selected route and stop at each station as it travels. However, unlike DRT systems, transit via APM systems is best suited for feeder and circulator applications, which are those involving more detailed

routes and passenger exchanges. The vehicles in an APM system are under 45 feet (14 meters) long and less than 9 feet (2.7 meters) wide, making them too small for line-haul service. The vehicles are generally self-propelled with rubber or steel wheels, but some are propelled by complex cable systems or utilize magnetic levitation rather than rails. APM cars can also travel up to 60 miles per hour and carry up to 10,000 passengers per hour per direction.

Personal rapid transit systems are much smaller in scale. They are intended to transport individuals or groups of up to six people traveling together via very small vehicles. The small, lightweight vehicles utilize short, direct routes along a dedicated aerial or underground cross-section guideway system and provide no intermediate stops. The PRT vehicles are 20 feet (6.1 meters) long at most and under 8 feet (2.4 meters) wide and often use battery power for propulsion. The maximum travel speed for most PRT vehicles is 20 miles per hour (32 kilometers per hour), and peak-hour capacity tops out at 4,000 passengers per direction each hour.

Advantages of ATS

Regardless of the specific type of ATS utilized, there are many intrinsic advantages to automated transit. For example, ATS vehicles offer higher average speeds than manned transit systems. Part of the reason is that when a driverless vehicle operates on a fully protected guideway or track, it can travel without impediments and thus progress at faster average speeds. The swifter travel time means that ATS vehicles also provide higher capacity capabilities because they can carry more passengers in peak hours than a similarly sized or configured system that travels at a lower average speed.

ATS presents potential cost benefits as well. While initial capital costs may be higher to acquire an automated control system with signaling, life cycle operating costs of an automated system should be much lower than manned systems because driver costs are not required. Moreover, the driverless feature provides added flexibility to the transit operations. For example, when ATS vehicles need to be added or removed from service to accommodate ridership fluctuations, it simply involves having a centralized control operator command the necessary vehicles, whereas the same situation in manually driven systems would require advanced driver and fleet scheduling and additional pay obligations to workers.

Service and safety are other important benefits of ATS. Automation enables efficiencies that provide passengers with more frequent service and shorter wait times, while advanced technologies facilitate passenger comfort and safety during transit.

Automated Vehicle Guidance Systems

Automated automobile guidance systems, also referred to as automated vehicle guidance (AVG) systems, are components that take over the tasks of the driver of a vehicle, such as maintaining speed, driving the vehicle, and keeping a safe distance away from other cars and objects. In addition to convenience, this technology is considered promising to improve road network traffic conditions and enhance safety. AVG systems are commonplace in warehouses and business facilities that rely on moving robots for product assembly. These systems have not been fully implemented in cars, although technology for driverless cars is under development. The

purported benefits of AVG systems are improvement of road traffic performance, safety, and comfort because the role of the driver is eliminated.

Driverless Cars

One type of technology used in automated guided vehicles (AGV) is called free ranging on grid (FROG). FROG vehicles are equipped with a computer that contains a map of the area in which the vehicle operates, such as a GPS system. The vehicle starts from a known location and uses the map to determine the route to its destination. Wheel revolutions are used to determine how far the vehicle has traveled. Off the roads and in the industrialized setting, these vehicles can be loaded with cargo and sent on their own to unloading areas without the requirement of human operation.

FROG can even be used in public transportation hubs to transport travelers from one location to

another. These systems operate similarly to elevators and, with the push of a button, travelers can be transported. As with vehicles that load cargo, a computer with a map and calibration models determine how far the system has traveled and when it must stop.

FROG technology can only be used in a limited area. Automated highways are being evaluated as a way of extending driverless technology to larger areas. Such roads designated for automated travel do not currently exist, although developers imagine they could work alongside smart cars, which use features such as adaptive cruise control to maintain speed and improve safety conditions. The highways would gather data on speed, road conditions, obstacles, and directions and report these findings to the cars as they travel. The systems would be able to interpret and react to the information as it is received.

Traffic Management

When multiple AVG systems are in use, such as at a loading facility, the vehicles must be equipped with traffic management systems to prevent them from running into each other. Zone control is the most popular and widely used type of traffic management because it is simple to install and easy to expand. Zone controls survey the area surrounding the vehicle and use a wireless transmitter to send a signal to a fixed area. Each vehicle on the floor is equipped with this technology. When the zone is clear of other vehicles, they can come and go with ease, but they stop when another vehicle is detected. Once the AGV in the zone has moved beyond the zone, the “clear” signal is sent to one of the waiting AGVs.

When a vehicle occupies a zone, the AGVs behind it cannot access that zone but rather the next completely unoccupied zone behind the lead vehicle. The leading vehicle must proceed into the next zone before the trailing vehicle can move ahead into its next zone. The system works in this procession to avoid collisions on the floor. If a vehicle can occupy a zone, however, it is allowed to move freely within that area making all necessary stops before moving on to the next unoccupied zone.

Similar to collision avoidance systems in automobiles, AGVs use collision avoidance sensors to avoid crashes. Such sensors include sonic radar, optical, which uses an infrared sensor, and bumper, which is a physical contact sensor.

An automated guided vehicle (AGV) transporting goods in an industrial setting. AGVs are used for limited applications in public transportation; more sophisticated vehicles, such as driverless cars, are in development.

In general, forward-sensing control is useful when the zone in question is a straight path rather than a curved trajectory. When an AGV senses a vehicle in front of it, it remains in place until the lead vehicle moves out of the range of the sensing devices. There may be long runs in which forward-sensing control can be used, reducing the expense of the traffic management system significantly. In the remaining areas of the path where there are divergence path and convergence path areas, a form of zone control is used. The vehicles respond to both types of traffic control, depending upon the area in which they are operating.

General Motors and Carnegie Mellon University researchers are working together to develop driverless cars and hope to bring one to the market by 2018. Advocates of driverless car technology point to improved safety by removing driver-related risk factors, which would also improve traffic conditions and reduce pollution. Many remain wary about the idea of automated vehicles hitting roadways, however. Aside from the fact that people enjoy driving cars, eliminating human judgment in the event technology fails can be dangerous.

Automated Vehicle Location Systems

Automated vehicle location (AVL) systems are systems built into a vehicle to track and report its location, for example, for the purpose of tracking and managing delivery vehicles and tracking the progress of their freight. They are similar to, but often differentiated from, event-activated tracking systems, which similarly track vehicle location but for the purpose of recovery after events such as theft or an accident. The technology is functionally similar and sometimes the same—many vehicles include both functionalities, whereas vehicles marketed to consumers use AVL-type technology associated with a theft prevention service that monitors location only in the event of an incident. AVL systems are used principally for fleet, delivery, and driver management.

Early AVL systems used triangulation to derive the vehicle's location, based on radio signals. Radio signals from the vehicle to two points with known locations could be used to determine the location of the vehicle's transmitter. Triangulation is an old (and sound) method of location detection and is still in use today by the enhanced 911 system of cellular phones in order to allow 911 dispatchers to determine the location from which an emergency call is made from a cellular phone, which is not tied to a fixed location the way a landline is. The known locations used in triangulation may include signpost transmitters, which is common on transportation routes like railways and highways.

In such cases, the vehicle receives a signal from the signpost transmitter as it passes and sends back an acknowledgment, which confirms the vehicle has passed that checkpoint. This system is often used by delivery companies in order to check a vehicle's progress against a schedule. The use of specific checkpoints makes the comparison of progress easier. This system continues to be used either on its own or in conjunction with Global Positioning System (GPS) tracking, since it works on legs of the journey where GPS signals are blocked, such as by surrounding mountains or other terrain features.

Today, use of GPS has become widespread and is used in most modern AVL systems. Unlike radio signals, GPS signals are not distorted or drowned

out by electrical noise. Like cellular phones, they benefit from using an infrastructure already in place, that of the satellite-based navigation system originally launched by the Department of Defense, and thus do not require infrastructure investments by the company developing or using the AVL system.

They are more precise than either the signpost transmitter system or the radio signal triangulation system and can track a vehicle's location in real time. The system as installed in the vehicle receives GPS signals from the satellite system confirming the vehicle's exact location, which is then relayed to the dispatching or monitoring system, either continuously or in response to an inquiry.

Maritime AVL systems today are nearly always GPS based. Previously, the Long Range Navigation (LORAN) system was used for maritime and aviation navigation, using low-frequency radio signals and fixed radio beacons. The most updated version of LORAN, LORAN-C, was discontinued by the U.S. and Canadian Coast Guards in 2010 in favor of GPS. Private-sector maritime AVL systems based on LORAN had largely been discontinued years earlier, and the brief automobile AVL system using LORAN, which only worked on the country's coasts where the coastal radio beacons were close enough, had been discontinued in the 1980s.

AVL systems have a wide variety of commercial and public-sector applications. They are commonly used to track public transport, and in some cities apps have been developed that allow the user to follow the actual location of a given bus or train in real time, minimizing uncertainty about departure and arrival times. They are commonly used to manage any large fleet of vehicles, land or maritime, including delivery fleets, public and school transportation, and emergency vehicles like ambulances and fire engines. AVL systems are useful for any service that manages a fleet of vehicles that are dispatched to particular locations rather than following specific routes, such as ambulances, police vehicles, or taxis, because the dispatcher can instantly see which vehicle is closest to the site where response is needed and has to inquire only as to availability. Sales forces sometimes use AVL systems to dispatch sales representatives to different customer appointments.

Typically, these systems overlay GPS location data on top of a detailed map or other display that

is updated in real time. Weather, traffic, or other information may also be included, depending on the needs and concerns of the service. A computer-assisted dispatch system may automate the dispatching process by locating the nearest idle vehicle or may make suggestions to the human operator.

Asset tracking systems can also be incorporated into AVL systems, as is common with trucking companies using detachable trailers. The trailer and truck are monitored with separate AVL systems, which facilitates better inventory management of the freight being transported by trailer and reduces the amount of freight that is lost in transit after being transferred from one cab to another.

Advanced AVL systems may be integrated with other systems that update the central dispatch system with information about the vehicle's performance and current state, including fuel levels and mileage, tire pressure, engine condition, ridership, or freight information as applicable, and whether the vehicle is currently en route to a destination or available to be dispatched. Driver hours can also be logged for personnel and wage purposes, and driver performance information can be tracked, such as total miles traveled, speed, dwell time, unscheduled stops, missed stops, or traffic stops. This information may be either directly monitored or derived from monitored information.

In some cases this data may be requested by law enforcement agencies in order to determine which drivers of various vehicle fleets may have been near a given location at a given time for purposes of finding crime-scene witnesses.

Automated Vehicle Monitoring Systems

Many of the current technologies used to monitor vehicle position and operational status, such as automated vehicle location (AVL) systems and automated vehicle monitoring (AVM) systems, fall under the more encompassing term *intelligent transportation systems* (ITS). These typically consist of an electronic device installed in a vehicle, or a fleet of vehicles, with software that tracks the location and collects additional data that can be sent to an operational base. All technologies incorporated in ITS have a similar evolution beginning in the early 1960s. The creation of the global positioning system (GPS) in 1973 by the U.S. Department of Defense was an offshoot of the Defense Navigation Satellite System (DNSS), which originally used 24 satellites.

Anyone (individual, commercial, or military) with a GPS receiver can access the transmissions that satellites continually emit indicating time and position. With a minimum of four satellites and navigation equations, the GPS receiver calculates distances and times from relative position changes. GPS vehicle monitoring systems involve the installation of an electronic device in a vehicle to enable the owner or a third party to track the vehicle's location (and also receive additional information about the vehicle). These automatic vehicle monitoring (AVM) systems also combine a communications component such as cellular or radio transmitters to communicate the vehicle's location to a remote user. Vehicle information can then be viewed using appropriate software.

Common Uses

AVM systems have a variety of personal and commercial uses; with the increase in fuel prices, the technology is advancing rapidly. Transportation sectors in which the technology has already been established include commercial cargo carriers, municipal passenger travel (buses), fuel transportation (tankers), construction industry fleets, agricultural vehicles, railroads, courier/shipping trucks, and rental vehicles. For personal vehicle use, an owner may use AVM technology to monitor a driver's speed, location, travel history, distance traveled, fuel use, accidents, and hard-braking events. This tracking of driver behavior and performance can be applied by an employer for employees or by parents

of teen drivers. It can also track the vehicle in the event of theft.

AVM systems are indispensable as tools for fleets of vehicles. One of the more common commercial uses is for fuel-use monitoring. AVM prevents fuel theft, misuse, or drain. The system also can prevent unauthorized vehicle use; it may assist in supervision of vehicle operation time and workers' hours. These tasks are enhanced with fuel tank sensors, driver recognition and license plate ID technology, container management, alerts if vehicle/driver is leaving a customized geographic perimeter, tracking of acceleration/deceleration events, trip time, trip type, seat belt use, and various predetermined engine readings.

Components of AVM technologies include vehicle-to-infrastructure (V2I) communications and vehicle-to-vehicle (V2V) communications systems. By exchanging anonymous, vehicle-based data regarding position, speed, and location, V2V communication enables a vehicle to sense threats and hazards with a 360 degree awareness of the position of other vehicles, calculate risk, issue driver advisories or warnings, or take preemptive actions to avoid and mitigate crashes.

Vehicle-to-infrastructure communication is the wireless exchange of critical safety and operational data between vehicles and highway infrastructure. Though intended primarily to avoid or mitigate motor vehicle accidents, it also enables a wide range of other safety measures. By incorporating data exchanged between vehicles and infrastructure elements to perform calculations that recognize high-risk situations in advance, drivers may be alerted and warned in advance. An example of this technology is the ability for traffic signal systems to communicate the signal phase and timing (SPAT) information to the vehicle in support of delivering active safety advisories to drivers.

Economic Impact and Future Technologies

Productivity, efficiency, security, and safety are of key importance in both commercial and public transportation. Transit agencies are using ITS for improved schedule adherence, more accessible passenger information, and more data for dispatch management and planning. The integration of intelligent features and autonomous functionalities in vehicles will lead to major economic benefits, including reduced fuel consumption, efficient use of the road network, and reduced personnel. Crash

avoidance technologies can reduce a large number of vehicle accidents. Vehicle control systems that automatically accelerate and brake with the flow of traffic can conserve fuel more efficiently than the average driver. Reductions in fuel consumption yield corresponding reductions in greenhouse gas emissions. All commercial transportation sectors prevent financial loss and benefit enormously by monitoring use of fuel.

AVM and other intelligent transportation systems and their applications are evolving rapidly. Currently, new technologies for AVM and intelligent transportation systems are being developed that may offer even greater efficiency, safety, and economic benefits. Camera-based Computer Vision, radar, Light Detection and Ranging (LiDAR), and ultrasonic sensors have been employed to support applications that require simple object detection, such as advanced driver assistance systems (ADAS), vehicle collision avoidance technology, and advanced traffic management systems. Other applications for ITS include vehicle-to-vehicle communications, autonomous vehicle support, truck platooning, and intersection collision avoidance. Ultimately, these technologies will support the next generation of autonomous vehicles, such as the Google self-driving car.

Automatic Terminal Information Systems

The Automatic terminal information system (ATIS) is a means used by many towered airports around the world to distribute essential weather and airport-related information to arriving and departing aircraft. Most ATISs utilize automated voice technology to allow busy air traffic controllers to quickly type a new ATIS message rather than manually record a voice message. Most airports in a single country utilize the same recorded voice and message format for ATIS content to ensure consistency in delivery and communication. Similarly, the order of information provided in an ATIS recording is always the same, although the specific content may vary considerably. The recordings are updated at regular intervals, typically shortly before every hour, and when there is an important modification to the existing recorded information, such as a change in runway or approach or a pilot safety notice.

Message Format

Every ATIS message includes the same key components, which are presented below in the same descending order.

The first item in any ATIS message is the airport or facility name followed by a letter designation that serves to identify the specific version of the message. Letters are assigned in order, progressing through the alphabet from A to Z with each update. The letter is used to confirm that the pilot is referencing the latest information during correspondence with air traffic control.

The time of recording is given next and is presented as Greenwich Mean Time, regardless of the airport or pilot's location. Recordings are typically made 10 minutes to 15 minutes before each hour. There is a slight delay before the recording is available via ATIS so there may be a very small window of less than two minutes when no ATIS information is heard.

The third item on each recording addresses winds. Winds can be listed descriptively using words like "calm" in conjunction with details about direction or they may be given as a combination of direction and speed. Wind direction indicates the magnetic direction from which the winds originate. The information makes it convenient for pilots to compare wind direction with the runway in use to determine headwind. Wind direction may also be listed descriptively as "variable" or as being variable between two directions. Wind speed is provided in knots and may be presented as a specific number alone or as a number gusting to another number.

Visibility is the fourth item covered in ATIS recordings. It is most commonly given in terms of statute miles (1,609 meters = 1 statute mile) versus nautical miles (1,852 meters). Many locations report any visibility greater than 10 statute miles simply as "10sm." Anything that negatively affects visibility, such as mist, haze, or smoke, is also reported. Since visibility has the potential to vary greatly depending on direction of viewing and sun interference, any significant variances in visibility would likely be noted as well. Wind direction and velocity must be reported from certified direct-reading instruments.

The next topic covered on the ATIS message is clouds. Because clouds occur in multiple layers, the message is reported from the lowest layer to the highest, using feet above ground level. The type of cloud base is also reported, such as "broken" or "scattered." If the cloud coverage is less than one-eighth of the visible sky, the cloud section of the ATIS message may simply indicate "clear." The cloud ceiling—above which aircraft may be unable to climb—is indicated by the lowest cloud level assessed as being either broken or overcast. Many ATIS systems use automated sensors to determine cloud status. Any indications of lightning, dense clouds signaling storm activity, and unstable convection clouds must be reported via ATIS.

The control tower at Ronald Reagan Washington National Airport in Arlington, Virginia. Air traffic controllers enter critical automatic terminal information system (ATIS) data for pilots into standardized messages that are usually updated hourly.

Temperature and dew point are reported in degrees Celsius. The smaller the spread between the two, the more humid the air will be, resulting in a greater likelihood of haze, mist, or low-level clouds. The altimeter setting is listed next and is measured by inches of mercury in ATIS reports; it is used to help pilots confirm appropriate elevations. Temperature and dew point should be reported from certified direct-reading sensors when available, while altimeter information always must be reported from certified direct-reading instruments.

Critical pieces of information provided by the ATIS reports address airport approach and runways in use. This section of the ATIS message indicates runway assignments and specific approach instructions for the pilot during takeoff or landing.

The final component of the ATIS message is the remarks section, where nearly any topic of interest to the pilot may be included. For example, the remarks portion of the message could issue a

reminder to pilots to read back call signs and runway assignments, contact ground control when ready for takeoff, or even to be aware of birds in the area. This section of the ATIS message may also contain information such as taxiway closures, runway surface conditions, holding delays, or temporary air zone restrictions.

Benefits for Stakeholders

Automatic terminal information systems can provide significant advantages for almost every participant throughout the air travel process. For the pilot and air crew, ATIS messages provide rapid, reliable delivery of important flight data that not only improves preparation and safety due to inclusion of more detailed data but, with today's digital ATIS systems, also relieves air crew of previously required transcription duties for routine control messages. Instead, the ATIS information can be downloaded at any time during the flight when it is most convenient for the pilot and saved as a record for future reference and repeat listening if needed.

The enhanced efficiency in the cockpit often translates into improvements in airline operations. For example, better preparation and communication can result in fewer scheduling delays. For passengers, the smoother operations and reduced air crew workload means they can generally expect more on-time air travel and increased quality of flight service.

In the control towers, the benefits of ATIS come from being able to deliver convenient and comprehensive messaging to flight crews with minimal effort while greatly reducing the congestion of messages being transmitted on the regular tower and ground control radio frequencies. By reducing the routine workload of air traffic controllers, ATIS enables them to devote more time to the specific needs of actively engaged arriving and departing aircraft.

For airline operations centers, ATIS offers a streamlined process for dispatching and archiving flight operations messages that can be used to prioritize activities and plan ahead for potential delays, weather diversions, and other situations.

Automobile Access Programs

Automobile access programs include a variety of regulatory strategies that limit or prohibit automobile travel. Some programs allow automobile traffic but limit it to certain hours of the day or to certain days. Still other programs restrict automobile traffic to commercial vehicles and the vehicles of residents. The most restrictive programs prohibit automobile traffic from a specific area, creating pedestrian-oriented zones within urban areas. These programs typically are part of a larger program, such as a downtown revitalization program or a local traffic management plan, and are authorized by city government.

Although opposition to these programs may be fierce, the benefits of a well-designed program are many and significant. Effectively administered automobile access programs can reduce traffic congestion, improve safety, and decrease harmful vehicle emissions.

Limited Access Programs

One method of limiting access is the institution of no-drive days. Generally, no-drive days are voluntary and are designed to improve air quality. No-drive days have been in use since the 1970s, particularly in cities in western states. Denver and Phoenix have implemented no-drive day campaigns during

the three to four winter months when air quality is at its worst. The no-drive day campaigns have been credited with reducing emissions by approximately 2 percent in these two cities.

Driving restrictions based on vehicle license plate numbers have been implemented with limited success in cities such as Beijing and Mexico City, but such programs are rare in the United States. Studies have found that such programs rarely result in significant reductions in traffic congestion or emissions. Two-car families merely exchange vehicles, and shoppers merely defer trips. Furthermore, a substantial number of vehicles such as emergency vehicles, taxis, delivery vans and trucks, construction vehicles, and vehicles used by professionals such as medical personnel are granted exemptions.

Pedestrian Malls/Streets

Automobile-restricted zones can sometimes refer to a complete closure of streets to vehicular traffic. Pedestrian malls can be grouped in three categories: those that eliminate all motor vehicle traffic (restricting deliveries to off-peak hours), those that allow some motor vehicle traffic at very low speeds, and those that close the street during certain times. Typical examples of the latter group include farmers markets and festival closings. Temporary pedestrian zones can be created inexpensively by blocking an existing street with signs or barriers. Creating permanent public space is more costly, ranging from \$100,000 to several million. These zones prove most successful in places with a high volume of pedestrian traffic prior to the imposition of automobile restrictions.

The earliest pedestrian malls were created in the late 1960s and early 1970s to combat downtowns' loss of income to suburban malls. For the most part it was a losing battle for the cities. While New York City was garnering headlines for transforming parts of 34th Street into a pedestrian mall, other cities were reversing the process. But pedestrian traffic in New York equals that of most European cities, and high pedestrian volumes are consistent throughout the city. Kalamazoo, Michigan, turned Burdick Street into a pedestrian mall in 1959, inspiring 200 other cities to follow its example. Kalamazoo reintroduced cars to its downtown in 2000, and again other cities, such as Raleigh, North Carolina, followed its example.

This portion of Manhattan's Park Avenue Viaduct made up part of the seven miles of streets reserved for bicycle riders and pedestrians during the city's "Summer Streets" program in 2012. That year, 250,000 people participated in the program.

Four decades after first closing a section of downtown's K Street to automobile traffic, civic leaders in Sacramento, California, reopened a couple of blocks of the city's pedestrian mall as an experiment. Businesses instantly saw more retail traffic. The city decided to spend \$2.7 million to reopen the area to cars in hope of repeating the success of the experiment.

The Example of New York

In 2007, the Michael Bloomberg administration launched PlaNYC to make the city more appealing to pedestrians and bicyclists. A study had revealed that crowding was generally detrimental to commerce and safety and a deterrent to pedestrians, particularly those in wheelchairs, parents with strollers, people with disabilities, children, and the elderly who all usually need more space for walking.

In response, the New York City Department of Transportation (NYCDOT) created Broadway Boulevard from 42nd to 35th Streets in the summer of 2008, providing a corridor of public gathering spaces along with a protected bicycle lane. Over 150,000 people participated in a program christened Summer Streets in August 2008 when NYCDOT opened a seven-mile car-free route from the Brooklyn Bridge to Central Park to bicyclists and pedestrians for three Saturdays in a row. New York's Central Park and Prospect Park are closed to vehicular traffic for most off-peak hours and on the weekend. In 2012, Prospect Park reduced the space for cars to a single lane and created two separate, dedicated lanes, one for pedestrians and one for bicycles. In 2013, Central Park doubled the width of the pedestrian lane to 14 feet and added an 11-foot-wide bicycle lane that organizes cyclists by speed.

Street closures have been implemented in other large urban parks as well. Golden Gate Park in San Francisco began closing John F. Kennedy Drive on Sundays in 1967 and has since expanded the closure to also include some Saturdays. Piedmont Park in Atlanta provided parking to visitors to the Botanical Garden in a garage built into a hillside, eliminated surface parking, and added entrances for walkers and cyclists. Research supports the view of parks providing sustainability benefits to cities through parks' green oases where residents can escape from the noise and pollution of cities.

The Ciclovía Model

Urban parks are not the only oases. Gaining in popularity in the United States is the *ciclovía*, a concept pioneered in Bogotá, Colombia, in the 1980s. A *ciclovía*, which literally means "bike path," closes a street route to automobiles and transforms city streets into a safe zone for residents to run, bike, skateboard, dance, and enjoy a wide variety of other recreational and social activities. The first *ciclovía* in the United States was held in the summer of 2007 in El Paso, Texas. As of 2011, more than 46 cities in the United States and Canada sponsored *ciclovía*. Some are sponsored by city governments, but many are organized by community groups. Among the largest are CicLAvia in Los Angeles, Sunday Streets in San Francisco, Open Streets Chicago, Open Streets Minneapolis, Atlanta Streets Alive, and Cyclovía Tucson. Baltimore's *ciclovía* project is almost as old as El Paso's, and the movement continues to grow.

Jackson, Mississippi, and Indianapolis are among the cities that hosted their first *ciclovía* in 2013.

Ciclovía, like other road closures, sometimes inspire protests from motorists and residents of neighboring communities, who fear traffic in other areas will become more congested, complain that cars will be diverted onto residential streets, and argue that merchants will lose money and museums and other attractions will lose patrons. But a broad consensus supports the events as a means of fostering healthy cultural interactions, economic development, and physical activity—characteristics of a thriving community.

Automobile Accident Avoidance Systems

Not that long ago, automakers were content with merely minimizing the impacts of accidents or investigating their causes, also termed amelioration and analysis. Avoidance differs from amelioration. Accident avoidance systems are proliferating in automobiles around the world, from backup cameras that allow the driver to see objects and people behind the vehicle to facial recognition software that notices a driver dozing and sends an alert signal to wake the driver. Adaptive cruise

control uses radar and lasers to adjust speed and preserve a safe distance between vehicles. Featured in advertising, avoidance systems sell well because any driver with any experience at all has at one time or another experienced a near miss or driven distracted.

An old technology from the 1970s is the event data recorder, the black box, debuted by Chevrolet on the 1974 Caprice Classic, which was among the first cars with airbags. The Caprice black box recorded airbag deployment and provided repairers and manufacturers with information about the results of the crash and its magnitude.

Active crash avoidance tools include the antilock brake systems (ABS) that keep tires from locking and skidding under hard braking. ABS also offers traction control, adjusting power to each individual brake as needed. Stability control is also a feature, and it uses a different set of sensors to track lateral movement, steering angle, and so on, and it can automatically apply brakes to keep the vehicle on the proper path.

Newer technologies are well beyond those that detect slippage. Collision mitigation and avoidance systems use sensors (radar, cameras, ultrasonic sensors, lasers) to track activity outside and around the car. The systems may decide the vehicle is approaching another too fast, in which case they will sound a warning, flash a light, vibrate the seat or steering wheel, or any combination of the above. Some Ford systems will prime the hydraulic lines in anticipation of a hard stop. The Toyota precollision system will prime the brakes and also tighten the seat belt. Mercedes, Volvo, and Infiniti systems brake for the driver. Debuted in 2012, Volvo in Europe and Asia has an airbag between the hood and windshield that deploys to cushion a pedestrian struck by the vehicle.

Blind Spot Monitors

Blind spot monitoring systems generally offer a warning light on the exterior mirror or pillar and may beep as well. The 2013 Ford Fusion offers cross-traffic detection, a combination of the rear-view camera and blind spot monitor. Nissan and BMW offer multiple cameras around the vehicle to give a bird's-eye view of the car's environment. Another avoidance tool is proximity detection that beeps as a vehicle gets nearer and nearer to an object.

Anti-Drowsiness Lane Departure

Lane departure systems offer warnings and either an alert or an automatic return to lane. Cadillac ATS and XTS not only beep and flash but also vibrate the seat. Mercedes and Infiniti brake to bring the vehicle back to the proper lane. In the future, power steering systems will automatically correct for lane departure. The trigger for lane departure systems is a nonsignaled lane change, and turn signal activation neutralizes the warnings.

Mercedes offers Attention Assist as an option. The system monitors various elements and notifies the driver when it is time for a break. Infotainment systems with voice capability reduce driver distraction.

Electronic Stability Control

According to the National Highway Transportation Safety Administration (NHTSA), electronic stability control (ESC) reduces accidents of all types by 15 percent. It measures speed and tilting of the vehicle around a curve and, when the vehicle deviates from the curve, slows the vehicle, brakes, and stiffens outboard shocks to return the vehicle to the appropriate path. Volvo and Mercedes lead the industry in automated technology. Mercedes has included vehicle stability systems as standard equipment on all models since 1999, and Volvo has one of the best electronic stability control (ESC) systems.

Adaptive Headlights

Adaptive headlights improve dark-road visibility. Some vehicles have automatic high-beam activation if it is dark enough. These headlights also sense an oncoming vehicle and turn themselves to low beam to avoid blinding oncoming drivers.

Adaptive headlights move with the driver's steering and provide improved visibility around curves. Adaptive headlight-equipped vehicles decreased claims 10 percent.

BMW and others offer infrared lighting for better night vision. With pedestrian detection, these systems can differentiate between humans and animals and notify the driver if something is crossing the road.

Autonomous Braking

Another technology is the autonomous braking system. Volvo, Mercedes-Benz, European Ford, and General Motors provide this technology. GM's

version, called Driver Assist, senses problems in the front or back of the vehicle and helps stop the vehicle; it is called Driver Assist, available in the 2013 Cadillac XTS, and it combines radar, cameras, and ultrasonic sensors controlled by a computer. Driver Assist also warns a driver that another car has entered the lane ahead and decreases the speed of the car if the cruise control is on. Driver Assist includes blind zone alerts and lane departure warnings.

Lexus is first in the world with an advanced pre-collision system (APCS), which uses cameras and radar and detects pedestrians in the vehicle's path and brakes the vehicle to avoid an accident.

Because left-turn accidents are the leading cause of death for motorcyclists, BMW has a pilot system called Left Turn Assist. In-car GPS detects that the vehicle is in the left-turn lane and scans ahead for motorcycles and cars, emitting a warning sound and displaying warning signals on the instrument cluster if one is detected. If the driver fails to stop, Left Turn Assist brakes the car to avoid a collision.

Volvo's Queue Assist stops the car and gets it back to speed in stop-and-go traffic. Volvo XC60s with City Safety Collision Avoidance System have 27 percent fewer fender benders, according to the Highway Loss Data Institute (HLDI), a subsidiary of the Insurance Institute for Highway Safety (IIHS). The Volvo system incorporates forward-looking laser sensors to locate and measure the speed of vehicles ahead. A loud beeping and a flashing dashboard light warn the driver to brake immediately to avoid a collision. Below 20 mph, the system automatically brakes the car. It can prevent collisions between two vehicles traveling at less than 10 mph difference. For speed differences greater than 10 mph, it cannot avoid the collision but it can reduce the impact. The result, claimed by Volvo and verified by the IIHS, is fewer accidents and fewer injuries. Lower insurance costs are a result too. The technology has potential in the future to work in high-speed as well as low-speed events, and that development would not only cut costs but save lives.

Vulnerabilities

Technology is not infallible, as indicated by the recall in 2014 of almost 44,000 2012–13 Honda Fit hatchbacks because the stability control software was not adjusting for oversized tires on the sport model, thus allowing skidding on turns. The Volvo City Safety system in the 2011–12 S60 had

a tendency to brake the car at low speed without apparent cause. There was no option to disconnect the system.

Accident avoidance systems, like any other part of the vehicle, are not foolproof. They fail due to dirty sensors, fogged cameras, malfunctioning radar—the general problems of advanced technology. When it has to be replaced, the cost is quite high. For one thing, the repair technician has to have specialized training and tools for working on an accident avoidance system. Also, accident avoidance systems do not make for a driverless vehicle. The driver still has to be alert and in control of the vehicle.

Benefits

A 2012 HLDI study found that forward collision avoidance systems and adaptive headlights reduce accidents significantly. Forward collision avoidance warns when a crash with a car ahead is about to happen. The same study found no accident improvement for lane departure warnings, which alarm when a vehicle drifts away from its lane.

The HLDI study found that autonomous braking and adaptive headlights were significant improvements. Lane departure warnings caused more accidents, not fewer. And there was no noticeable benefit to blind spot detection and park assist. The major improvement in claims was in damage to other vehicles more than to the accident avoidance-equipped ones. The study did not examine frequency of collision claims, but it revealed a slight reduction. Injury claims also decreased somewhat.

The Mercedes and Volvo systems without autonomous braking lowered crash rates but not as much as versions with both forward collision warning and autonomous braking. Presumably, drivers do not react as efficiently as machines and are less able to avoid accidents.

Claims for vehicles with adaptive headlights fell by up to 10 percent on Acura, Mazda, Mercedes, and Volvo models. All but one brand had a marked decline in injury claims. All four systems benefited most types of insurance coverage, and they worked in more situations than researchers expected, but there was no clear explanation why.

Buick and Mercedes lane departure warning systems increased collision and property damage claims, but the increases were statistically insignificant. It was also possible that the data were insufficient because drifting off the road is uncommon.

The technology also may be ineffective when lane markings are not clearly visible. For insurance purposes, the technology was of the future, not of today's claims. The institute did not study lane departure systems that do not allow a vehicle to leave its lane, but there was some anticipation that such systems would have a greater impact than simple warning systems just as autonomous braking enhanced the effectiveness of forward collision warning systems. The less the vehicle relied on the driver and the more it relied on itself, the safer it seemed to be.

The HLDI study examined forward collision avoidance systems on Volvo, Mercedes-Benz, and Acura, and found that Mercedes and Acura automatic braking systems reduced insurance claims 14 percent, and Volvo automatic braking reduced claims by 10 percent. Vehicles with only warning but no automatic braking had only a slight reduction in claims.

Vehicles with lane departure warning systems in some cases had higher claims, possibly because the cameras were not working properly or because the warnings were so frequent that drivers ignored them or turned the system off.

Accident avoidance technology is most often optional and limited to luxury brands. In 2012 avoidance systems formerly reserved for luxury brands began appearing in more mainstream vehicles. The 2012 Ford Taurus offered forward collision avoidance as an option.

Vehicle-to-Vehicle Communications

The NHTSA is emphasizing vehicle-to-vehicle (V2V) communications that will allow vehicles to talk to each other, collecting information from other vehicles and the road. Information may pertain to accidents ahead, pedestrians in the road, or red light-running vehicles. The vehicle's onboard electronics can assimilate the information and establish a safe speed or advise of emergency maneuvers. The NHTSA reports that 80 percent of crashes are due to driver error. Volvo is committed to V2V, having a goal of zero crash deaths in Volvos by 2020. And the future of V2V naturally is the fully autonomous vehicle, driverless cars either in "road trains" or individually. Taking out the driver eliminates road rage, rubbernecking, and other driver errors.

Automobile Accidents and Prevention

The 2007 population of the United States was roughly 300 million people. The 200 million licensed drivers had 255 million vehicles; 71 percent of American adults drive to and from work. Between 2000 and 2005 more than 6 million auto accidents occurred in the United States. Approximately 2.9 million people a year were injured during that period, and more than 42,000 a year were killed. Vehicle accidents kill approximately 115 people every day in the United States, and about 20 percent of the dead were passengers.

Motorcycle accidents in 2007 killed 5,000 people. Motor vehicles killed 4,600 pedestrians that year: 25 percent were in intersections, 9 percent involved large trucks. Even in lightly populated Nevada the annual death toll from accidents is over 400 people, 37 percent in cars and 32 percent in light trucks. Seventy-seven nonmotorists and bicyclists die in an average year.

The Insurance Institute for Highway Safety (IIHS), which uses the Department of Transportation Fatality Analysis Reporting System data, notes that 2011 saw 32,367 traffic fatalities. The American Automobile Association (AAA) estimates vehicle accidents cost \$162 billion a year, over \$1,000 a year per American. Causes include inexperience, speeding, intoxication by alcohol or drugs, and simple recklessness.

Driver Error

Driver error accounts for more than 80 percent of fatal and injury crashes in Ireland, probably close to the same in the United States. Driver errors include tailgating, failure to signal, and drifting from one's lane. Driver inattention/lapse accounts for a million crashes a year in the United States. In a Nevada study, 51 percent of vehicle accident deaths were in accidents where the vehicle left the roadway. Drivers err when they behave badly by tossing cigarette butts, honking, driving with bright lights or with no lights, trying to squeeze ahead in traffic. Speeding and not wearing seatbelts also qualify as errors contributing to traffic accidents.

Intoxication

Driving while intoxicated is a major driver error. Blood alcohol levels above 0.08 percent contributed to a third of the fatalities recorded in the Nevada study. Impaired driving kills on average nearly 30 Americans each day. That is one every 48 minutes. The 2010 total was 10,228 people, 31 percent of all traffic fatalities. The annual cost is over \$51 billion. In 2010, 1,210 children died in traffic accidents, 211 in alcohol-related incidents (17 percent of the total.) Of these, 211,131 were in the vehicle driven by the impaired driver. Intoxicated driving kills more young people, with one-third of the alcohol-related fatalities in 2010 involving persons between ages 21 and 24, 30 percent age 25 to 34, and 25 percent age 35 to 44. Twenty-eight percent of motorcyclists

The Insurance Institute for Highway Safety (IIHS) conducted tests on a 2010 Hyundai Tucson GLS using this crash test dummy at the IIHS Vehicle Research Center in April 2010. According to the IIHS, there were 32,367 traffic fatalities in 2011.

killed in 2010 had a blood alcohol content (BAC) of 0.08 or greater. Motorcyclists age 40 to 44 account for 44 percent of fatalities.

Drowsiness

The AAA Foundation for Traffic Safety finds that people who sleep six to seven hours a night double their risk of a drowsy/sleep-induced crash compared with those sleeping eight hours or more. Sleeping less than five hours elevates the risk four to five times. An Australian study indicates that being awake for 18 hours produces impairment equivalent to a BAC of 0.05, while 24 hours equals a BAC of 0.10. A BAC of 0.08 is legally drunk in most states.

The National Sleep Foundation (NSF) in 2005 reported that 168 million people, 60 percent of adult drivers, had driven drowsy in the past year, with 37 percent, or 103 million, saying that they actually fell asleep while driving. Thirteen percent of the dozers reported being asleep at the wheel once a month or more. The NSF *Sleep in America* poll of 2001 found that over a fourth (27 percent) of respondents indicated they had driven drowsy to or from work more than once a week, and 4 percent admitted they were drowsy drivers just about every day.

Eleven million drivers (4 percent) had an accident or near accident due to dozing or feeling greatly fatigued. According to the National Highway Traffic Safety Administration, driver fatigue accounts for 100,000 police-reported accidents involving roughly 1,550 deaths, 71,000 injuries, and \$12.5 billion in losses. The numbers might be low because there is no breathalyzer test for sleepiness, there is no police training or state standard for identifying drowsiness, self-reporting is not reliable, and other causes such as alcohol may overshadow drowsiness as a contributing factor. Countries that have more consistent reporting procedures than the United States indicate that drowsy driving is a cause of 10 to 30 percent of all crashes.

Among adults between 18 and 29, 71 percent are likely to drive drowsy compared to 52 percent aged 30 to 64 and 19 percent age 65 and over. Men are more likely than women (56 to 45 percent) to drive drowsy and 2 to 12 percent more likely to fall asleep while driving. More likely than average to doze and crash are commercial drivers, shift workers, drivers with children in the household, and those with undiagnosed disorders such as sleep apnea and insomnia.

Sleep deprivation and fatigue contribute to other accident-causing behaviors such as inattentiveness, stress (42 percent of drowsy drivers), impatience (32 percent), and speed (12 percent.) Only 22 percent of drivers pull off the road when drowsy.

Inexperience

Younger drivers are more likely to drive drowsy than older ones. Because of inexperience, teens are less likely to judge the risk of danger or recognize hazardous situations, more likely to speed and follow too closely, and less likely to wear seat belts. Younger drivers are also more likely to be involved in risky

and sometimes fatal behaviors. Vehicle accidents are the leading cause of death among teens. In 2010, every day, seven people aged 16 to 19 died in motor vehicle crashes. That was a total of almost 2,700 in 2010, and there were 282,000 emergency room visits by teens due to automobile accidents. Of male fatalities between ages 15 and 20 in 2010, 39 percent were the result of speeding, and 22 percent had been drinking. Only 54 percent of teens in 2011 claimed they wore seat belts when riding with someone else, and in 2010, 56 percent of fatalities after drinking and driving were not wearing seat belts.

Teens are three times more likely, based on miles driven, to be in a fatal crash than are drivers aged 20 and older. Vehicle accidents are the cause of 36 percent of all deaths of teens. The total cost of motor vehicle injuries for the 14 percent of the population aged 15 to 24 is \$19 billion for males, \$7 billion for females, 30 percent of the total cost for males, 28 percent for females. For drivers aged 15 to 17, the cost was \$34 billion in property losses, medical bills, and related costs in 2006. That year, 15- to 18-year-old drivers had 974,000 accidents that injured 406,427 and killed 2,541.

Prevention

Accident prevention checklists recommend that drivers practice defensive driving, stay away from drunk drivers, and don't drive drunk or tired, slow down, and get driver safety training. Well-established accident prevention methods include remediation therapy for offenders, random breath testing, and a high level of publicity.

Law enforcement is a key preventive. Speed limit enforcement reduces accidents, given that speed may contribute to upward of a third of all fatalities. Sobriety checkpoints reduce crashes about 9 percent by taking drunk drivers off the streets. Ignition interlocks installed in the vehicles of prior offenders that won't allow operation by anyone with an unsafe BAC (0.02–0.04 percent) can reduce arrest rates for impaired driving by 70 percent.

Preventive measures for teens include graduated driving licenses (GDL) that allow teens to learn to drive under more controlled conditions. The GDL reduces fatality and injury crashes by up to 38 and 40 percent, respectively, for 16-year-olds. The GDL requires parental involvement, which in itself can reduce foolish and fatal driving behavior. Other accident prevention measures include mandating

lower centers of gravity for high-profile vehicles, roll cages, safety glasses, and insurance rates based on performance.

Safety Testing

When prevention fails, minimizing consequences entails using safety equipment, such as air bags, crumple zones, energy-absorbing bumpers, seat belts and child restraints. Highway modification to incorporate roadside guardrails as crash barriers and crash cushions as well as other safety features will reduce accidents. Beyond these safety measures, safer vehicles become important. Safety research labs exist at various levels.

Crash tests are a critical tool for reducing loss of life and property from vehicle crashes. Crash tests destroy vehicles to verify that standards for vehicle safety are appropriate. There are several types, including frontal impact tests, side impact tests, rollover tests, offset tests, and roadside hardware crash tests.

A frontal impact test crashes the vehicle into a solid concrete wall at a set speed. Offset tests entail a collision of only part of the front of the car with a barrier or another vehicle. Offset tests involve the same crash impact as full frontal impact tests, but the impact affects a smaller area of the car, which has to absorb the full impact. Side impact tests are vital because side impact collisions produce high fatality rates due to the minimal crumple zone to absorb the collision, meaning that the occupants take the brunt. Rollover tests evaluate a vehicle's ability to maintain structural integrity, particularly from the roof supporting pillars. Roadside hardware crash tests evaluate crash cushions and crash barriers' ability to protect passengers. Other roadside hardware whose potential for damage requires test and minimization includes sign posts, light standards, and guard rails.

SAFE Laboratories of Santa Barbara, California, has for almost two decades been devoted to research and analysis of automobile safety and crash testing. Sled testing and full-scale vehicle crash tests incorporate front, rear, and side impacts at speeds of 35 miles per hour (mph) and greater. Areas tested are passenger safety systems, restraints, seating systems, padding, structural damage, and air bags. SAFE uses onboard instrumentation and high-speed cameras and other testing devices for real-world accident simulations.

The U.S. government's Insurance Institute for Highway Safety (IIHS) is a nonprofit scientific/educational agency. The Highway Loss Data Institute (HLDI) is also a government organization and it supports the IIHS. Both agencies have insurance carrier backing. The IIHS rates vehicle crash worthiness and provides an online searchable database by make and model or by type. It also provides a list of prior winners of awards for crashworthiness and safety of occupants in a crash. These awards rest on five tests; all five favorable outcomes earn a rating as "Top Safety Pick." The tests are (1) a moderate overlap front test to evaluate effectiveness of the crumple zone, (2) a small overlap front test for cases with minimal crumple zone impact, (3) a side test of protection when struck in the side by a pickup or SUV, (4) a rollover test, and (5) a rear test that tests restraint prevention of whiplash. The IIHS also tracks incorporation of crash avoidance systems such as collision warning and automatic braking, and it tests bumpers as well as insurance loss by model. The IIHS has been conducting research since 1969.

Another research organization, this one at the federal level, is the National Highway Traffic Safety Administration (NHTSA), a division of the U.S. Department of Transportation. The NHTSA replaced the National Safety Bureau in 1970 and is responsible for safety programs under federal laws of 1966 and after. Its mandate is to reduce economic losses as well as deaths and injuries from traffic accidents. It sets and enforces vehicle and vehicle equipment performance standards and provides grants to state and local governments for highway safety programs. It also deals with vehicle defects, fuel economy standards, promotion of child restraints and seat belt use and air bags, and reduction of drunk driving. Its research arm examines traffic safety and driver behavior to improve safety.

Crash test programs throughout the world are devoted to making vehicles safer for owners and drivers and to giving potential purchasers safety performance data, a significant consideration in purchasing both new and used vehicles.

The type of crash test is important. When the IIHS introduced the small overlap test in 2012 some previously high-performing vehicles fared poorly. Toyota was among those with a long tradition of five-star IIHS safety ratings but poor ratings for the new test, which evaluates the force of a collision

on areas that are relatively weak. But 13 or the 18 midsize family cars tested survived the side impact test satisfactorily and maintained the top rank in the older tests. The IIHS intentionally added the small overlap test to evaluate historically high-scoring vehicles, the ones that the manufacturers had designed and developed with the four older IIHS tests in mind.

The IIHS found in 2009 that, for vehicles with good front protection, small overlap crashes generated nearly a fourth of frontal crashes that produced serious or fatal injuries to front-seat passengers. The small overlap test recreates a collision between a front corner and another vehicle, a utility pole, or a tree. A fourth of the front end hits a 5-foot-tall rigid barrier at 40 mph. Many vehicles' crumple zones do not protect fully against this sort of accident, and the impact can push wheels and suspensions into the passenger compartment or spin the car and force the driver's head away from the air bag.

Driving is a dangerous affair, and manufacturers and safety testing organizations can do only so much to make vehicles accident resistant. The key element in accident prevention is the driver.

Automobile Culture

The American public's love affair with the automobile has influenced economic, residential, recreational, popular culture, and many other aspects of life in the United States and around the globe. Although automobiles first became popular at the turn of the 20th century, a series of developments that coalesced during the 1950s ensured that this trend became a phenomenon. A variety of factors, including the development of the interstate highway system, the sprawl of urban areas, increased mobility of the population, and growing leisure time, all led to the embrace of the automobile culture. As American trends increasingly influenced global preferences, the automobile culture became an international occurrence.

Background

Shortly after 1919, automobile pioneer Henry Ford predicted that any working individual who desired a car of his or her own would soon be able to purchase one. By 1950, over 25 million registered

automobiles were on the road. Although this number of automobiles represented an all-time high, many of these vehicles were built before World War II and were in poor repair. By the end of that decade, however, the number of registered automobiles had risen to nearly 70 million, with many of these late-model vehicles built after the conclusion of war-imposed rationing and other restrictions. By 1960, one in six Americans was employed directly or indirectly as a result of the automotive industry, and the inauguration of the interstate highway system in 1955 greatly increased the use of private vehicles for leisure travel.

This rapid embrace of automobile culture changed many aspects of American life. More cars and better engineered roadways made it possible for many to flee beyond municipal borders, and a new suburban lifestyle developed that increased the number of individuals who commuted a distance from their homes to work. Low-interest home loans available to servicemen returning from World War II made the suburban lifestyle a reality for many younger Americans, and this population shift in turn created the need for new shopping centers, supermarkets, gas stations, and other commercial entities and conveniences. This rapid growth of suburbia resulted in more than 33 percent of Americans' living in such areas by 1960. During the previous decade, 11 of the United States' 12 largest cities saw population declines, with only Los Angeles, in many ways the archetype for embracing automobile culture, seeing growth in the number of its residents.

Impact

As traditional cities lost population to their suburbs, these urban areas saw declines in tax revenues and the city centers deteriorated. As pressure for the desegregation and integration of public schools increased, "white flight" also grew, as many parents sought to ensure that their children stayed in schools with predominantly white student bodies. The rapid sprawl of suburbia made the expansion of public transportation systems economically prohibitive, which in turn sped up the growth of the automobile culture that had spurred the decline of many rapid transit systems.

As traditional city centers withered, new types of businesses that fully embraced the automobile culture were created. Before the 1970s, few Americans

ate outside the home with any regularity, except for meals prepared at home and carried to another location for consumption. Drive-in restaurants became popular during the 1950s—passengers reluctant to leave their cars could remain in their automobiles while carhops brought items ordered directly to the customer. Other restaurant chains, intending to cater to the mobile customer of the times, originated during the 1950s and 1960s, with industry icons such as McDonald's, Burger King, Kentucky Fried Chicken, and Wendy's all originating during this period.

These businesses used consistent menus nationwide, as well as easily recognizable logos and signs that could be spotted from the road, to cater to a clientele that was dependent on the automobile. Drive-in movie theaters also grew in popularity in response to the love affair with the automobile. With a large outdoor screen, ample outdoor parking, individual electronic speakers, a concession stand, and a projection booth, drive-in theaters catered to families and other moviegoers, although their popularity had declined by the 1980s.

Shopping malls developed in suburban areas to permit their newly affluent residents to avoid the inner-city experience entirely. Free-standing, and often enclosed and climate controlled, shopping malls supplanted traditional downtown shopping areas, further leading to urban decline. Often anchored by popular department stores, shopping malls were usually accessible only by automobile and featured abundant and no-cost parking as a way to entice shoppers. As shopping malls grew larger and more popular, they helped other retail areas go into rapid decline, which limited greatly the shopping options for those who did not have access to an automobile. As concerns regarding urban sprawl and the desire to engage in environmentally friendly practices grew, problems with the automobile culture came to be recognized.

Consequences

As more Americans began using automobiles, roads and highways were built to cater to them. This in turn enabled the growth of suburban areas, which also created the need for new businesses that catered to the newly affluent residents of these outlying areas. The allure of the suburban lifestyle, combined with white flight from the cities, meant that these areas grew at a rapid rate, and

new businesses sprang up to cater to them. These businesses, which included restaurants, shopping malls, drive-in theaters, and others, were designed to appeal to owners of automobiles and, intentionally or not, excluded those who did not have access to a car.

As concern for the environment grew during the 1970s, the negative influences of the rapid growth of the automobile culture began to be examined. Suburban sprawl, crowding, inefficiency, and the decline of central city districts all were associated with automobile culture, and increased calls came for better public transportation options and more urban planning. Despite this resistance to automobile culture, the siren song of the vehicle remained strong, causing many initiatives intended to curtail its use to fail. Many Americans remain dependent upon their automobile for access to retail shopping, entertainment options, and employment opportunities.

Automobile Design

In 1924, automotive sales in the United States had reached the saturation point, and to maintain unit sales, Alfred P. Sloan Jr., the head of General Motors, suggested annual model-year design changes to motivate car owners to buy replacement vehicles each year. The idea of a new model every

year originated with the bicycle industry. Critics called Sloan's strategy planned obsolescence, although Sloan preferred to call it dynamic obsolescence. This strategy had long-term effects on the automobile business, product design, and eventually the American economy.

Smaller companies could not match the pace and expense of yearly restyling, and Henry Ford did not like the annual model-year changes because he believed in the engineering principles of simplicity, economies of scale, and integrity of design. In 1931, General Motors outpaced Ford's sales and dominated the automobile industry until the 21st century.

Frequent style changes transformed the field of automotive design, creating the necessity of using a body on frame instead of the lighter but less flexible monocoque—or external skin support—the design most European automakers used. Many design innovations progressed into the 21st century, but automobile designers followed certain core ideas as they produced their yearly models, including safety, fuel efficiency, air pollution, computerization, automatic parking assist, and global positioning systems, as well as predicting and designing automotive innovations.

Automobile Design: Safety Seat Belts—Inflated and Otherwise

In 1965, Ralph Nader published a book called *Unsafe at Any Speed* that motivated automobile companies and designers to add and improve automobile and truck safety features, including seat belts, padded dashboards, collapsible steering columns, and improved bumpers.

In 1959, automobile maker Volvo introduced the three-point safety belt over the skepticism and resistance of the automobile industry and the general public. Initially, Volvo installed the three-point safety belts only in Sweden, but by 1963 all Volvos, including the ones destined for the United States market, included front-passenger three-point belts. Later, automotive engineers began designing seat belts with more comfortable straps and better force limiters. Seat belts of the future will feature computers and microprocessors controlling the way a seat belt works before, during, and after a crash.

Design engineers, including those at Ford, have worked for decades to improve seat-belt safety. An

Visitors viewing energy efficient design features in a car engine under development at Argonne National Laboratory in 2013. New government standards will require automakers to build vehicles that average about 35 miles per gallon by 2016.

engineering team at Ford Research and Advanced Engineering developed the first inflatable rear seat belt, which Ford introduced as a premier safety feature beginning with its 2011 Ford Explorer. According to Ford, its design team accepted the challenge of making an inflatable rear seat belt that combines the working of a conventional seat belt with some of the safety features of a front-seat air bag. Ford engineers created a tubular air bag that folds like an accordion so that it can be stored inside the seat belt. An instant after a crash, the inflatable bag breaks through the seat belt fabric as it fills with air and expands sideways across the body and shoulders of the person in the belt. The inflated belt helps distribute the energy generated by the crash across five times more of the passenger's body than a traditional belt. As well as

enhancing safety, the air bag also adds comfort by contributing cushioning to the seat belt.

Possibly with an eye on the National Highway Traffic Safety Administration (NHTSA) statistics saying that only 61 percent of rear seat passengers in the United States are using their seat belts, Ford projected that the additional safety and comfort would motivate rear-seat passengers to use rear seat belts in the Ford Explorer more often. Eventually Ford plans to offer the inflated seat belt in all of its cars worldwide, although it faces challenges in adapting the design for cars other than suburban utility vehicles (SUVs), and there are some safety concerns for passengers in booster seats.

Air Bags

Next to seat belts, automotive designers have made the most significant safety advances in air bag technology. The NHTSA calculates that the seat belt–air bag combination is the most effective safety combination available, reducing the risk of death by 61 percent. It estimates that since 1998 air bags have saved nearly 28,000 lives.

The NHTSA has required new vehicles to have advanced front air bag systems since September 1, 2006. Since 1990, 291 people have been killed by air bags, and so designers have configured the newer air bags to turn on and off based on the weight and position of vehicle passengers.

Although Mercedes-Benz has installed air bags in all its models since 1986, the U.S. government did not require air bags for the driver seat and front-seat passenger until 1998 for automobiles and 1999 for light trucks. Swedish car maker Volvo introduced side-impact air bags in the mid-1990s, and BMW has also pioneered advanced air bag technology. The BMW M3 featured as many as eight air bags, and its 7 Series offered knee air bags that protect the legs and help prevent the driver from sliding down and forward during a crash.

Designers have created air bags shielding the pelvis, chest, and head that could be deployed from the door, seat, or roof of the vehicle. In some vehicle models, side curtain air bags protect the head; some remain inflated for as long as 5 seconds during rollovers.

General Motors pioneered the dual-depth passenger-side air bag in which the manner of inflation depends on variables like seat position, crash

severity, size of passenger, and whether or not the seat belt was fastened. In newer Volvo models, dual-stage air bags work on a slightly different principle that adapts inflation speeds to specific conditions. The air bags fully and rapidly deploy in severe crashes, whereas a less severe crash triggers a slower 70 percent inflation.

Other safety features include head injury protection, antilock brake systems, all-wheel drive and traction control, and electronic stability control systems.

Automobile Design Trends

Twenty-first-century design trends feature short windows that make the roof appear lower and the entire car seem sleeker. Rounded roofs and fewer right angles create a sense of seamlessness where the glass and metal meet. However, the rounded designs pinch the windows tighter and make it more difficult for the driver to see where the front and back of the car end. According to Max Wolff, director of Cadillac exterior design at General Motors Corporation, consumers like all of the metal surrounding them because it makes them feel safer, even if that feeling is an illusion.

Aggressive design once confined to sports cars has become an important element. Both older and younger vehicle buyers prefer more aerodynamic designs, which boost fuel efficiency. In an aerodynamic design, the tail of the vehicle is higher than the front, creating a smooth wedge that cuts through the air. More dramatic wedge shapes further increase fuel efficiency, even though a higher trunk lid makes it harder for the driver to see out the back window.

Automobile Design and Fuel Efficiency

An automobile's fuel efficiency is the relationship between the distance traveled and the amount of fuel the vehicle uses while traveling. The energy in fuel is required to overcome wind resistance, tire drag, and other factors in propelling the vehicle and in providing power to vehicle systems such as ignition or air conditioning. Driver behavior can affect fuel economy; for example, sudden acceleration and heavy braking both waste energy. Vehicle fuel consumption is a major factor in air pollution, and importing fuel is a large part of America's balance of trade, so driver behavior affects the American economy and the environment.

America's first fuel efficiency standards were implemented in 1978 as a response to the 1973 to 1974 oil embargo, and they roughly doubled the fuel efficiency of new cars in the 10 years following the embargo. Over the next two decades, the standards stagnated and produced very little improvement in fuel efficiency. In the 21st century, the United States is getting back on the fuel-efficiency track by requiring automakers to build vehicles by 2016 that average approximately 35 miles per gallon and emit roughly 30 percent less pollution. When they are fully implemented, these new standards will save more oil and reduce more tailpipe pollution than any other existing government program.

The Obama administration is extending fuel efficiency and pollution standards for passenger vehicles and setting the first standards for commercial trucks. President Obama announced plans to move forward with new fuel efficiency and pollution standards, and the U.S. Department of Transportation (DOT) and Environmental Protection Agency (EPA) have been directed to establish joint fuel efficiency and pollution standards for new cars and trucks. They will establish new fuel economy and pollution standards for light-duty vehicles, a category including cars, SUVs, minivans, and most pickup trucks, through model year 2025. The agencies will also set the first-ever fuel efficiency and global warming standards for medium- and heavy-duty trucks including delivery vans, city buses, and long-haul tractor-trailers, through model year 2017.

Automobile Design: Computerization

Modern automotive designers and engineers have a powerful tool—computer-aided design, or CAD software—to help them imagine, design, and refine their ideas. Patrick J. Hanratty helped pioneer the use of CAD to automate repetitive drafting chores for General Motors in the mid-1960s. The use of CAD systems in automotive design expanded significantly over the years as computer costs decreased and technology expanded.

Today's automotive engineers and designers use CAD systems to quickly draw their designs, work with other experts, and simulate actual vehicle performance. Designers can even create visual prototypes for consumer research and marketing and, by streamlining the development process, auto

manufacturers can reduce the time from drawing board to assembly line by rolling out new models faster than ever before. CAD automotive systems can help identify and eliminate design faults. Computer simulations take 3D models through a variety of situations including high speeds, harsh weather, accident impacts, and everyday wear and tear. Designers have made cars safer by using CAD to design and test seat belts and air bags and to improve visibility, energy transfer and absorption, and vehicle control and handling, including anti-lock brakes.

The combination of computers and cars also took other forms. Volkswagen (VW), in conjunction with Stanford University, built an autonomous Audi TT that can drive at high speeds without a driver. Using real-time software lets Shelley, Stanford's robotic racecar, achieve reaction times of just a few milliseconds. Scientists at VW's Electronics Research Lab hope that technology from Shelley might eventually be used to help drivers control their cars during emergency maneuvers, preventing crashes.

Other automobile companies like Ford and Lexus are building auto-parking technology into their high-end sedans, and Toyota equips some of its models with the Toyota Monster Xbox All-Terrain Gamer. Mercedes brought out the Mbrace app, which, acting like a key fob, allows its owner to locate, lock, and unlock the car. Carsharing pioneer Zipcar takes the idea a step further by locating and reserving a Zipcar and then programming the horn to honk so the renter can find it more easily. Chrysler uses a 3G module to turn its cars into mobile WiFi cafes with e-mail capabilities.

Automatic Parking Assist

In 2003, Toyota Motor Corporation launched the intelligent parking assist system (IPAS) for Lexus models in the United States, designed for reverse parallel parking. Using an onboard computer and built-in front and rear cameras, the system estimates the size of the parking space and maneuvers the vehicle appropriately. Front and rear sensors detect the proximity of nearby vehicles. A dashboard display shows the image of the parking space. In one of the few human interventions, the driver determines the exact position of the vehicle in the lot by maneuvering arrows on the screen. The IPAS takes over steering control and parks the vehicle. By 2006, the system could recognize minute objects

and it featured parking sensors. Newer versions parallel and reverse park.

In January 2011, Ford introduced its Active Park Assist parallel-parking technology as an affordable option in the Ford Focus, Explorer, Escape, and Flex and in its Lincoln MKS and MKT. The technology uses an ultrasonic-based sensing system and electric power-assisted steering to position the vehicle, calculate the optimal steering angle, and quickly steer the vehicle into the parking spot.

Global Positioning Systems

Throughout the decades, automobile technology advanced and automakers shifted their focus from basic transportation to designing features like the global positioning systems (GPS) that made vehicles safer, more comfortable, and more easily operated.

A GPS consists of space, control, and user segments. The space segment consists of two dozen satellites funded and controlled by the U.S. Department of Defense that orbit the Earth twice every 24 hours at approximately 10,900 nautical miles above the Earth's surface. The control segment is a series of monitoring stations located at different sites on Earth that update and correct errors in the navigational messages of the satellites.

The user segment is a receiver that receives radio waves from the satellites in orbit to determine how far away it is from each satellite by keeping track of the time it takes for a radio wave to travel from the satellite to the receiver. Four satellites are used simultaneously to pinpoint the receiver's position on Earth. Information from the first three satellites narrows the range of possible locations to two points, one of them usually indicating a point not on the Earth. A fourth satellite is used to confirm the target location.

The accuracy range of a typical GPS receiver is about 50 feet, which may not be practical for locating a small object like an automobile. Differential GPS (DGPS) is a system that improves the accuracy of the GPS receiver to about 7 feet. Several reference GPS receivers are placed at stationary locations with known coordinates and these receivers compare their known locations to the location information they receive from the satellites. The receivers broadcast the range errors they detect from each other and from every satellite and a DGPS receiver can pick up range

error information and correlate it with the satellite signals it receives to discover its true position. The accuracy depends on how fast the reference receivers broadcast their signals.

Installed in a car, a GPS can provide useful information about the car's position and the best travel routes to a given destination by linking to a built-in digital map. A monitor in the car shows the relevant part of the map and the driver can enter the target location; the computer then calculates the best route and displays it instantly. A GPS can respond to user preferences and map a route that avoids highways or avoids local roads and, if it is detailed enough, can also provide the locations of the nearest gas station, supermarket, restaurant, hotel, and ATM machine. Some GPS units can issue voice directions to guide drivers as they travel.

GPS also tracks distances traveled on a particular trip, vehicle mileage, and speed. It keeps a record of driving activity, including the address of each destination, names of streets traveled, and how long the vehicle remained at each location to allow owners to monitor the use of their cars by other drivers. Some systems issue warnings when the car is speeding and when the car is approaching a speed trap, and other systems monitor the car condition and issue warnings when the battery is low or when it is time to change the oil.

When a car is stolen, GPS can aid in its recovery. If it is integrated with the automobile security system, GPS can notify the car owner by phone or e-mail when the car alarm is triggered and indicate the car's location. An owner can contact the GPS unit from outside the car using a cell phone or the Internet, and can start the car engine remotely and unlock the door, solving the problem of accidentally locking himself out or the locks freezing in bad weather.

In addition to its applications in private vehicles, commercial shipping companies use GPS to speed the delivery of cargo by allowing companies to track their fleets, record the movement of their trucks, and control route planning. Car rental companies can equip their cars with GPS technology to find stolen rental cars and charge customers for dangerous conduct like speeding.

The original analog Electro Gyrocompass system used an accelerometer to navigate using stationary navigation, as the GPS system was not yet generally

available, but Honda claims to have created the first navigation system starting in 1983 and leading to its general availability in the 1990 Acura Legend. As early as 1985, a U.S. company called ETAK introduced its own digital map navigation system with a geographically limited effective range. Research on Honda's digital map navigation system resumed in 1987 after a three-year delay.

By 2013, automobile manufacturers and improved technology offered many global positioning services and companies that were eager to manufacture them. Magellan, Tom Tom, and Garmin are some of the most popular global positioning systems sold in the United States and around the world.

The availability and accuracy of the global positioning systems provide increased safety for vehicles on highways, streets, and mass transit systems. GPS helps eliminate many problems with the routing and dispatch of commercial vehicles and facilitates managing mass transit systems, road maintenance crews, and emergency vehicles. GPS technology is advancing very quickly. New models are being developed every year to correct problems in older versions, focusing on improved accuracy, better reception, and even more user-friendly features.

Design Futures

Designing the cars of the future is a global activity, and master's degree students from the Royal College of Art's Vehicle Design Course in London have contributed their imaginations and innovation to the global design pool. Some of their ideas include a car that ages with its owner and, unlike its mortal owner can be reincarnated; an Audi that builds itself with robotic 3D printing technology; and a camper vehicle that is a cross between a motor home, a yacht, and a power boat. Other ideas include the Lexus Impulse 2033, an open-top three-seater in which the driver sits between his or her two passengers and a nocturnal car with glass auto tint panels, electroluminescent panels, and bright xenon lights.

Australian journalist Antony Funnell and other vehicle visionaries have speculated about vehicles that can brake, steer, and accelerate under optimal freeway conditions without human driver help. Eventually, a vehicle could be entirely robot and computer controlled and respond to a driver getting in and directing it to drive home.

Clicking from search engines to vehicle engines, the internet company Google has been working on a combination of hardware and software that could make the driverless car a reality in a decade or so. In 2012, Google announced that its driverless test vehicles had logged more than 311,000 miles without incident or accident. In an interview, *Time* magazine editor-at-large Harry McCracken emphasized that before Google's cars are consumer ready, ordinary cars will be able to efficiently park themselves inside a garage and come to drivers when summoned. He said that there are already cars on the road that can parallel park automatically.

Larry Burns is professor of engineering practice at the University of Michigan, former head of research and development for General Motors, and advisor to Google's driverless car project. He cites a technology called lane keeping that enables a car to keep itself in the correct lane and a feature called collision warning, that enables a car to avoid an obstacle in the road. Cars are equipped with speed range adaptive cruise control so drivers can keep a safe space between vehicles in front of them. Companies like General Motors are developing a feature called super cruise in its future models. Daimler is offering Distronic Plus, which resembles super cruise.

According to Burns, tailored and driverless vehicles will free drivers for more essential activities and force a restructuring of society in terms of energy, roadway safety, land use, and climate change. Fully automated cars will be a link in a larger system needed to support an eventual, complex and sophisticated society system of driverless cars; many of the components needed to construct and operate a system for driverless car technology already exist. Once the system is in place it will be capable, affordable, safer, and self sustaining.

Burns predicts that cars will be 75 percent lighter with 90 percent fewer parts. They will connect by a communications infrastructure web that will support many driving capabilities, conveniences, and features. He predicts that current energy problems, road safety issues, and urban congestion will dramatically subside and that drastically smaller cars will enable people to move more safely and efficiently.

Automobile Driver Warning Systems

According to U.S. Department of Transportation statistics, 32,367 people died and 2,217,000 were injured in motor vehicle crashes in 2011. To reduce these numbers, the Department of Transportation created the Intelligent Vehicles Initiative (IVI) to help drivers avoid hazardous mistakes. As part of the IVI, automobile manufacturers have expanded their focus beyond improving the crash-worthiness of their vehicles to include developing and installing automobile driver warning systems in them. These driver warning systems include collision avoidance technology and backup, drowsy driver, and lane-keeping systems.

Crash-Avoidance Technology

The term *crash-avoidance technology* refers to motorized-vehicle equipment that includes numerous features such as adaptive headlights that improve night vision around corners and curves, forward collision warning systems, backup warning systems, emergency brake assistance, lane departure warnings, and blind spot detection.

Already in use in Europe, crash-avoidance technology debuted in the United States in 2007, when Volvo, Lexus, Mercedes, and other automobile manufacturers pioneered its use. Ford used technologies, including Driver Alert, Lane Keeping Alert, and Lane Keeping Aid, in its 2013 Explorer. The National Highway Traffic Safety Administration (NHTSA) identified 68 vehicle models that featured lane departure warning, forward collision warning, or both, in the 2012 model year, an increase from just 45 vehicle models in the 2011 model year.

Forward collision warning systems use sensors like cameras, radar, or a technology called Light Detection and Ranging (LiDAR) to pinpoint potential rear-end or head-on collisions. Some

systems have automatic braking. Volkswagen used Front Assist on the 2011 Touareg and in 2012 it introduced Proactive Occupant Protection, which closes windows and retracts safety belts to remove excess slack if the system detects potential for a forward crash.

Backup Warning Systems

The safety advocacy group Kids and Cars estimates that every week in the United States two children are killed and 48 are seriously injured simply because a backing driver did not see them. Most back-over accidents happen in residential driveways or parking lots and more than three-quarters of the time a parent or a close relative is behind the wheel. Back-over accidents are so commonplace because every vehicle has a rear blind area that can't be seen from the driver's seat. Passenger cars have a range of blind zones, depending on the size of the car and the drivers, but the blind zones behind larger, popular vehicles are uniformly large. The blind zone behind a minivan is about 25 feet and the area increases to 50 feet behind some pickup trucks.

Backup warning systems can use radar or ultrasonic transmitters and receivers, beepers, and computer systems facing to the rear of the vehicle to detect objects in its path; however, backup warning systems containing cameras that are installed within the vehicle itself work better and are widely available from several competing electronics manufacturers. With a camera system, when a driver shifts into reverse, the screen shows a wide-angle view of the rear, a view superior to the one seen through windows and mirrors.

Newer vehicles can be purchased with backup warning systems, often custom made, but drivers with older model vehicles can also have backup warning systems installed. Aftermarket cameras, that is, cameras that did not originally come with the vehicle, can be incorporated into the navigation systems of vehicles. The aftermarket camera system typically use a video screen built into a replacement rearview mirror, an added monitor for the existing mirror, or a flat screen that mounts to the inside of the sun visor.

A small video camera can be built into a license plate holder or mounted in a trailer hitch receiver or on a car's bumper. Some systems are wireless, but most feature wiring that winds through the

vehicle from the camera to the video display and to the vehicle's electric power system.

In addition to revealing children or pets, a camera mounted near or in the rear bumper can make fastening a vehicle to a trailer hitch less of a chore. A camera pinpoints the exact location of the hitch and requires far less directions and second-guessing on the part of the driver and others trying to fasten the hitch.

According to *Consumer Reports*, none of the backup warning systems is perfect. The parking sensor systems cannot accurately pinpoint every safety hazard. The systems that use a camera built into an inside mirror seem more practical because the driver looks naturally into the mirror to back up, but the view is often small or blurred and add-on mirror displays can be cumbersome. Though some cameras have narrow viewing areas and others fog up easily, a camera system is better than a beeper or a proximity sensor.

Drowsy Driver Alert Systems

A 2011 AAA Foundation for Traffic Safety survey revealed that 96 percent of the people polled believe that people should not drive when they are so sleepy that they cannot keep their eyes open, but in the same survey one-third of those polled said that they had driven while drowsy.

Drowsy driving causes more than 100,000 crashes, 40,000 injuries, and 1,550 deaths every year according to the NHTSA. Automobile manufacturers are installing drowsy driver alert systems into growing numbers of vehicles to help reduce the deaths and injuries linked to drowsy drivers. Mercedes-Benz implemented an attention assist system that creates a driving habits profile and compares it to current driving data from the car's sensors to measure the driver's alertness. When the driver deviates from his or her personal norm, the system sounds a warning chime and displays a coffee cup icon.

Audi, Cadillac, BMW, Volvo, Buick, and Saab also have drowsy driver alert systems. To determine wakefulness, Volvo's system analyzes the driver's proximity to cars ahead and whether the driver stays in the proper lane. Saab's Driver Attention Warning System uses a voice alarm. If a driver is dozing, the car announces, "You are tired." If the driver does not respond, Saab sends a second warning that says, "You are dangerously tired!"

Stop as soon as it is safe to do so!" The driver's seat also vibrates to jar him/her awake. Saab also has an onboard computer that uses facial recognition software to determine if a driver is drowsing. The system focuses night vision cameras on the driver's face to analyze slackening facial muscles and eye blinking patterns to see how long the driver's eyes stay closed between blinks. Once the system concludes the driver is sleeping, it sounds an alarm to jolt him/her awake.

Ford's technology package includes what it calls a "Driver Alert System," which warns a driver when the software detects a pattern of drowsy driving, such as weaving within the lane boundaries. For the first warning, Ford's designers chose a soft chime and then to display the dashboard message "Rest suggested." If the problem persists, a second louder chime sounds and a new message appears: "Rest now."

Second-generation drowsy driver alert systems will feature high technology. Independent companies are perfecting systems that can safely wake up a drowsing driver, including blowing puffs of air on the back of a dozing driver's neck, vibrating steering wheels, and automatic steering that guides a driver back into the correct lane. Until these technology systems are widespread and more affordable, commonsense cures like a good night's sleep will reduce accidents and fatalities.

Lane Keeping Systems

Lane keeping systems installed in cars, trucks, buses, and other vehicles can dramatically reduce accidents caused by inattentive driving, making highways safer and lowering human casualties and insurance expenses.

Lane departure warning systems work somewhat differently in different models of vehicles. Most systems have cameras that are designed to see markers used to outline road lane markings and they are capable of distinguishing between yellow and white markings. All systems use sensors that detect a car drifting out of its lane and alert the driver with a popup on the vehicle's display panel or by sounding a buzzer. If the driver does not correct the drift, the software is then supposed to engage the power steering and turn the car back toward the center of the lane.

When a driver uses a turn signal, the lane departure warning is disabled, but otherwise the warning system is active. Lane departure warnings can alert

both sleepy and wide-awake drivers that they are not paying enough attention to their position in the road. Most of the time, lane keeping systems can be found fully installed in new cars, but some companies offer systems that can be retrofitted into older vehicles.

BMW featured a lane departure warning system in its 5 and 6 series, using a vibrating steering wheel to warn the driver straying out of the correct lane. General Motors introduced its lane departure warning system to alert the driver with an audible tone and a warning indicator on the dashboard, on its 2008 Cadillac STS, DTS, and Buick Lucerne models. Volvo featured the Lane Departure Warning System and the Driver Alert Control on its 2008 model year S80, the V70, and the XC70 executive cars. Its lane departure warning system uses a camera to track road markings, along with other sensor systems designed to increase driver safety by pinpointing problems with the driver, the car, or the roadway.

Lane keeping technology has its benefits and drawbacks. As the technology advances, drivers may pay less for insurance for vehicles with lane departure systems; insurance companies usually reduce rates for drivers with special safety features in their vehicles. Lane keeping systems may be a costly initial investment, but they will reduce the cost of the vehicle over its lifetime. When the lane keeping technology works it saves lives, and its enthusiastic adherents predict that it will become the norm instead of a novelty.

The present lane keeping system technology still has its limitations, despite the increasing number of automobile technology companies that are creating and improving it. When road conditions are unsuitable, as during heavy rainfall or on curves, the lane keeping technology fails to sense highway markings and remains dormant. When the sun is at a low angle, the sensors have a more difficult time producing accurate readings.

The National Highway Traffic Administration has not yet fully endorsed lane keeping technology because its engineers and safety inspectors believe that additional evaluation and research into the lane keeping systems needs to be conducted before the administration can fully recommend it to the public.

Automobile Drivers, Disabled

Disabled automobile drivers are an increasingly prevalent reality throughout the country. This fact has necessitated taking a close look at what can be done to maximize their ability to drive safely and successfully. Society has become more aware of this need and more sensitive to the situation of handicapped drivers.

The terms *disabled* and *handicapped* are virtually synonymous and are typically used interchangeably.

Both refer to individuals who are impaired in some way. The impairments can be psychological but are most often physical. Since the word *handicapped* has been used negatively in the past, the terms *disabled* and *disability* are usually considered preferable. These terms are used by advocacy organizations and can thus be taken as the current default. “Handicapped” still remains in common usage, though, and is becoming more acceptable again as it is employed in a respectful manner.

Society used to presume that disabled persons could not drive at all. As a result, those with disabilities were typically marginalized and excluded. As society has become more inclusive, there has been a corresponding understanding that physical challenges do not have to stand in the way of driving. With the right accommodations, successful use of motor vehicles can be achieved. Of course, the nature of the accommodations depends upon the nature of respective disabilities, such as impairments of vision, hearing, and physical mobility.

Vision

Visual acuity is a critical element of driving. To be effective while in transit, it is necessary to see the road ahead, other cars, pedestrians, traffic lights, walk signals, and any hazards. Not being able to see these elements well can slow a driver’s reaction time, potentially imperiling their own safety and the safety of those around them.

For this reason, drivers are examined for visual impairments before being allowed to operate a motor vehicle. Every state in the United States has specific requirements in this regard, and anyone not meeting those requirements will be denied a license. One example is Alaska, where everyone has to have at least 20/40 vision in both eyes in order to be permitted to drive. However, those with vision problems can still obtain a license if corrective lenses bring their eyes to compliance with the 20/40 standard. They are permitted to drive only when wearing the corrective lenses, ensuring that the standard is fulfilled consistently. Alaska denies driver’s licenses to individuals with visual acuity that is below 20/100 but may grant them on a conditional basis for those whose sight is tested at somewhere between 20/100 and 20/40. Conditions include a formal review by an optometrist and restrictions such as the kinds of vehicles the person can operate and the times each day when they can drive. The restrictions are

intended to protect the safety of everyone in and around the vehicle being operated.

Hearing

Hearing loss is a disability that affects people of all ages. Of course, it affects older individuals disproportionately, a fact that becomes relevant in light of the fact that tens of millions of drivers in the United States are 65 and over, according to the U.S. Department of Transportation.

The origin of hearing loss varies with each individual. It may be a result of ongoing exposure to loud sounds, from rock concerts to construction. It may also be the result of a genetic condition, such as X-linked hearing loss, which is transferred from mother to baby at conception. Lack of oxygen during prenatal development and premature birth can also be contributing factors, as can illnesses like otitis media, an inflammation of the middle ear.

Impairment of hearing loss is typically classified as mild, moderate, severe, or profound. The first two can be substantially helped with hearing aids, which may be of assistance in severe cases as well. If an individual experiences profound hearing loss, electronic devices are unlikely to make a substantial difference.

The degree of hearing loss, and the extent to which it can be corrected with a hearing aid, substantially affects a person’s ability to drive. If a person cannot hear horns of other cars, they may not get that audio warning of potentially dangerous situations. They might even not hear another car driving near them or pulling out of an adjacent parking place. Additionally, hearing loss can mean a decreased ability to differentiate between sounds and screen out unimportant ones. This can mean that individuals with hearing impairments are actually more distractible by common sounds and may therefore be at risk when driving in noisy areas.

Correspondingly, states typically test hearing as part of the licensing process. They can first test individuals without use of a hearing aid. If the person fails that test, they can try again with a hearing aid. If they meet the standard with a hearing aid, they will be granted a license that requires them to wear the hearing aid while driving. If they still do not meet the standard, it is at the Department of Motor Vehicles’ discretion whether they can operate a vehicle. If the decision is in the person’s favor, a state like New York will insist that they have a

full-view rearview mirror installed on their car or truck, because being better able to see other vehicles will compensate for lessened audio perception from hearing loss.

Physical Mobility

When the term *handicapped drivers* is mentioned, many people immediately envision drivers with physical mobility issues. This is because mobility issues are often the most visible. A person who has eye or ear problems may not be distinguishable from the general population at first glance. However, someone in a wheelchair or walking with a cane tends to be noticed immediately. Disabilities in physical mobility can include problems with hands, arms, legs, and feet. A person might have lost an arm or leg and needs to compensate with the remaining limbs when driving. Alternatively, they may have a condition, such as a clubfoot,

making manipulation of a car's gas and brake pedals a challenge. Some conditions result in individuals' having insufficient reach—simply put, they can't reach the steering wheel and the pedals simultaneously.

Fortunately, all of these challenges can be addressed through orthopedic accommodations. These can include adding devices to pedals to bring them closer to feet, or adding backing to seats to bring a person with limited reach closer to a steering wheel. They can also include left-foot accelerators for those who have lost their right leg, and vice versa.

State Departments of Motor Vehicles are not permitted to discriminate based on any of these disabilities per se. A driver's license will be granted if the person applying can demonstrate their abilities during examinations, which include road tests. Passing those tests is key: if accommodations are

This disabled driver makes use of assistive technologies, including a collapsible wheelchair model and a specially modified car, in order to drive independently. The car shown features manual braking located on the steering wheel, along with an acceleration knob, rather than floor pedals. The 60-inch access aisle reserved by the striped markings along the perimeter of the handicapped parking spot is also essential, as it gives the driver enough room to assemble the wheelchair and maneuver him or herself into it.

needed, a successful examination will result in a conditional license requiring those accommodations when driving.

Parking and Ramps

For a handicapped automobile driver, getting a license and securing any accommodations they need to drive successfully is much of the battle. However, many of them will be driving to shopping malls, schools, and business, making two other factors key to their experience. One is the presence of accessible parking places. These are designated by blue paint on parking lot surfaces and by special signs. Their requirements are established by the Americans with Disabilities Act (ADA) and enforced by the U.S. Department of Justice. Key among them is the inclusion of a 60-inch (5-foot) access aisle to accommodate the disembarking and loading of wheelchairs to and from vehicles.

The ADA also specifies requirements for wheelchair ramps. These ramps can be of tremendous convenience to drivers with disabilities as they approach and enter a building after getting out of their vehicle. Individuals who use canes or walkers can find them to be instrumental, since stairs may be difficult to manage for them. According to the ADA, ramps should have a 1:12 slope, since this gradient prevents wheelchairs from sliding backward while ascending. They should also be free of defects that might cause wheel problems or tripping.

Conclusion

Society's attitude toward handicapped automobile drivers has certainly improved. The common view toward them now is one of inclusion and acceptance. Because of that, their situation is improving in every respect. Accommodations are being developed to make driving with disabilities progressively more viable. Other people are realizing that disabled drivers simply want to travel like everyone else and that they are responsibly using the devices and tools they need to do so.

Going forward, this is likely to result in additional considerations becoming prevalent. For example, businesses will probably provide more handicapped parking spaces so all their customers will feel welcome. Ramps will also become more common, as will wider doorways that can accommodate wheelchairs without difficulty.

Some businesses may even go the next step, posting online maps of their properties so disabled drivers can quickly find handicapped parking places. Within cars, improved mirror systems and amplification devices can offer further assistance. Greater customization of cars to accommodate a variety of disabilities may also become more widely available.

Automobile Drivers, Elderly

In the coming years, dramatic increases in the number of and proportion of the population that is elderly will have significant impacts on the transportation system and transportation policy. Though elderly drivers drive less than younger drivers, their impact on the transportation system may be less predictable than that of younger drivers, who are more often tied to travel patterns centered on the work commute and fixed work hours and days. In addition to the impacts to aggregate travel demand, the ability of elderly drivers to drive safely is of concern to policy makers. This latter concern has led to the implementation of screening tests for license renewals and vehicle and transportation system changes designed to limit the number of vehicle crashes caused by

elderly drivers. This may lead to the cessation of driving for some, which can lead to deterioration of mobility and greater dependence upon friends and family as well as on public services.

Over time, people in the United States and other industrialized countries have become more dependent upon the automobile for most transportation needs. As successive cohorts of drivers have aged, they have driven more frequently and for more miles than the elderly of previous generations. In addition, better health care for the elderly has allowed more elderly drivers to drive at older ages than previously. The first of the baby boom generation (the generation born between 1945 and 1964) will become elderly in the next few years. This generation has been more automobile dependent than any previous generation and therefore increases in this population will have significant impacts on the transportation system in the years ahead.

According to population projections produced by the U.S. Census Bureau, between 2015 and 2060, the number of people aged 65 years and older will increase by 93 percent (compared to 30.8 percent for the population overall). In 2060, over 22 percent of the population of the United States is projected to be aged 65 years or older (compared to 14 percent in 2010) and 612 million people will be aged 85 years or older. All industrialized countries will experience these same patterns of change, resulting in substantial increases in the number of elderly drivers. Because the growth in the population will include many more women drivers than in previous generations, questions remain as to the extent of the impacts on the transportation system.

For most age groups, the difference in driver licensure rates for men and women is less than 5 percent (with men more likely to drive than women). This is not so for the oldest age groups. Some women who drove in younger ages may give up driving as they age and their cognitive abilities and visual acuity decline. Women are also more likely to give up driving more readily as a result of deterioration of health. However, much of the gap in driver license holding between elderly men and women is primarily a result of generational characteristics.

These now elderly women had licensure rates lower than that of men during their working ages, and by 2009, 72.8 percent of elderly women and 88.6 percent of elderly men were licensed to drive. These gaps in licensure between elderly women and

men are likely to disappear as women of the baby boom generation, who have held licenses at rates similar to men, are likely to continue to drive even after entering retirement age.

Impacts on Travel Demand

Elderly drivers have both positive and negative impacts on transportation demand. For instance, most elderly drivers are no longer in the workforce and thus their travel patterns are no longer arranged around work commutes. In the aggregate, this helps alleviate peak travel time congestion. At the same time, elderly drivers may be traveling for leisure or to access other daily activities and thus help increase the amount of traffic during other than peak work commute travel times.

Driving Abilities, Safety, and Loss of Mobility

In order to efficiently and safely operate a motor vehicle, drivers must use a set of critical driving skills, many of which may decline with age. These critical driving skills influence how drivers interact with other drivers, plan trips, and maneuver on the road. As individuals lose physical and cognitive abilities, these critical driving skills may become compromised. In addition, treatments for medical conditions that may not otherwise be problematic may impact driving ability.

While the number of elderly drivers involved in crashes is smaller than the number of drivers of younger ages, on a per driver or per miles driven basis, elderly drivers have higher accident rates than all but the youngest drivers. Partly as a result of frail health prior to involvement in vehicle accidents, elderly drivers have the highest fatality crash rates on a per miles driven basis. These concerns about elderly driver capabilities and resulting higher accident rates have led to the development of laws for testing vision and cognitive ability for older drivers.

In modern industrial societies, access to a car is necessary for many daily activities, such as going to restaurants and grocery stores, health care providers, and leisure activities. In areas where public transportation may not be available or preferred for the elderly, automobile transportation may be just as important for social interactions as well. Loss of the ability to drive marks a decline in the ability to interact socially and otherwise, especially in areas where the transportation network is designed primarily for the automobile. Therefore, understanding

who nondrivers are and where they live may be an important part in planning for medical, welfare, and public transportation services.

Automobile Emissions Controls

Automobile emissions are a chief source of harmful air pollution in many parts of the world, but several technological advances have helped limit the damage caused by toxic automobile emissions. These

technologies include the catalytic converter, computerized emission control systems, exhaust gas recirculation systems, secondary air injection systems, and positive crankcase ventilation systems. Much of this technological innovation was motivated by the need to meet new environmental regulations, and as car ownership and miles driven are predicted to continue to increase around the world, such controls help mitigate the potential damage caused by increased automobile use.

Regulation

An automobile powered by an internal combustion engine using hydrocarbon fuel emits pollutants, including carbon monoxide (CO), nitrogen oxides (NO_x), and hydrocarbons (HC), during normal operation. In the early years of automobiles, they were not considered a major source of pollution because so few were on the roads. However, as automobile ownership increased, particularly in the 1940s and later, more people became aware of and concerned about the toxic substances in automobile exhaust and their effect on the environment, and technological change was largely motivated by the need to meet the legal requirements of new regulations.

In the United States, California was the first state to enact pollution controls, motivated in part by geographical and atmospheric conditions in the Los Angeles Basin that made it particularly vulnerable to smog. The Bureau of Air Sanitation, created in 1960, set standards for air quality, and the Motor Vehicle Board began to regulate tailpipe emissions. The first emission-control devices were approved in 1964, including several versions of a catalytic converter. Although these early devices were failures, they did pave the way for successful designs; the catalytic converter is now a standard emissions control device and led to regulations banning the use of lead as a gasoline additive.

The first national legislation aimed at pollution control was the 1963 Clean Air Act for America; in 1965 the Clean Air Act was amended to include regulation of automobile emissions. (The original act focused on industrial pollution.) Leaded gasoline was phased out in the United States from 1975 to 1986 to reduce lead pollution and also because leaded gasoline interfered with the operation of catalytic converters. Exhaust gas recirculation (EGR) was introduced in 1973 in order to meet

Environmental Protection Agency (EPA) nitrogen oxide emissions standards, and electronic emissions control systems were also introduced to meet EPA standards.

Emissions Control Technology

The oldest automobile emissions control device still in use is the catalytic converter, which was required on all new cars in the United States beginning in 1975 and is also used on vehicles such as motorcycles and trucks. A catalytic converter consists of a substrate, usually a ceramic or metal honeycomb; a washcoat, such as silicon dioxide; and a catalyst, usually platinum. The three-way catalytic converter is now standard for most automobiles. It converts three types of exhaust pollutants—nitrogen oxides, hydrocarbons, and carbon monoxide—into harmless substances: nitrogen oxides to carbon dioxide, nitrogen, and water; and carbon monoxides and hydrocarbons to carbon dioxide and water vapor. The first catalytic converters were called two-way catalytic converters because they did not affect nitrogen oxides.

Modern cars include a computerized emissions control system, which reduces harmful emissions and helps the car run more quietly. This system consists of an engine control computer, which receives information from a network of sensors in the car and sends signals based on that information to the car's ignition, fuel, and emission control systems. This system regulates both tailpipe emissions (hydrocarbons, carbon monoxide, etc., caused by incomplete combustion in the engine) and evaporative emissions (caused by fuel evaporation).

Exhaust gas recirculation (EGR) is a method to reduce the emissions of nitrogen oxides by recirculating exhaust gas back to the engine cylinders. By thus diluting the intake air and fuel mixture with inert exhaust gases, the peak temperature of combustion is lowered and the combustion rate slowed, thus reducing nitrogen oxide emissions, which are produced by the reaction of nitrogen and oxygen at temperatures over 2,500 degrees Fahrenheit. Early EGR methods caused loss of engine power and rough idling, but these problems have been largely solved by more modern systems integrating EGR with the spark advance system; however, some people believe that EGR reduces gasoline mileage, thus indirectly increasing rather than reducing air pollution, but this is generally believed to be a

relatively minor factor. There are several different EGR systems in use, but the most common uses an EGR valve to control the passageway between the exhaust and intake manifolds, allowing exhaust through when it is open.

A secondary air injection system improves engine efficiency and thus reduces the amount of hydrocarbons (unburned fuel) in the exhaust. Automobiles are powered by the combustion of gasoline in the presence of oxygen, so the induction chamber could be considered a primary air injection system. A secondary air injection system builds on this principle by introducing air into the exhaust system to encourage combustion of unspent fuel and also makes the car's catalytic converter work more efficiently. Aspirated air injection systems were developed first, but a pumped air injection system is the standard today.

The PCV, or positive crankcase ventilation, system is a method of controlling the toxic gases, or "blowby," from the crankcase; these gases include both unburned fuel and toxic by-products of combustion. To prevent these gases from building up in the crankcase, the PCV system introduces air into the system to flush the gases from the crankcase and route them into the intake manifold, where they can be burned by the engine. Because this introduction of air reduces power, the PCV valve is necessary to control the amount of air introduced into the system. When an engine is idling and producing little blowby, the PCV valve is nearly closed and only a small amount of air is allowed to flow through the system; when the engine is running at high speed, producing lots of blowby, the PCV valve is at its maximum opening; this control is provided through the automobile's computer system.

Automobile Engines

Automobiles are a ubiquitous part of millions of people's lives. However, those automobiles' engines and the agencies that regulate those engines remain a mystery to most of the public. Internal combustion engines have dominated the automobile industry since before Henry Ford saw his first motorized carriage. These engines have been popular in part because of their relative mechanical simplicity. However, this may not always be the case, as there is much pressure to develop technologies that may replace the petroleum-burning internal combustion engine. Federal agencies and acts of Congress have been put in place in response to pollution emitted by automobile engines. The Clean Air Act, the Department of Transportation, and the Environmental Protection Agency all serve to regulate, among many other things, the fuel efficiency and emissions of automobile engines.

Types

Since the introduction of the first engines at the advent of the Industrial Revolution, the vast majority of mechanical power has been generated in roughly the same way. Simply put, a power source moves either a turbine or a piston. That mechanical motion is then either directly harnessed or converted into electrical energy.

While we may see different technologies utilized in the automobiles of the not-too-distant future, at

this time the vast majority of auto engines use internal combustion engines, and most of those engines use fossil fuels. While automobiles have made great technological strides since they first came on the market in the late 1800s, the basic components of their engines remain largely intact. The average automobile's internal combustion engine operates by igniting fuel in the high-pressure, high-temperature compartment called a combustion chamber. This high-pressure ignition causes what is essentially a tiny controlled explosion. This explosion then moves a piston. The movement of that piston is turned into either mechanical energy to move the vehicle or electricity for more refined tasks. It is mechanically possible for a conventional internal combustion engine to have anywhere from one to 16 pistons (cylinders). However, the vast majority of cars have either four or six pistons, and pickup trucks and larger personal vehicles may typically have anywhere from six to 10 pistons.

Until recently, nearly every vehicle on the road possessed an internal combustion engine that burned fossil fuels (gasoline or diesel fuel). However, in our era of enhanced environmental awareness and high gas prices, the general public is starting to demand vehicles that draw power from other sources of fuel. Some of these alternative fuels may continue to operate using internal combustion engines. Examples of these include vehicles that burn ethanol, refined vegetable oil, and biodiesel. Other possibilities may include models that are entirely electrical and require no internal combustion whatsoever. These vehicles may pull their power directly from the greater electric grid, solar cells, or various types of electrical fuel cells.

Policy and Pollution

The majority of laws introduced regarding automotive engines involve pollution prevention in one way or another. American air pollution laws are by no means the strictest in the world, but they are very important on the global scale. American laws set a certain standard for vehicle emissions because automobiles gauged to American specifications are sold globally. In the United States, automotive emissions standards are managed by the Environmental Protection Agency (EPA). Relating to automotive pollution, EPA sets emissions performance standards. These standards set thresholds above which limits for conventional pollutants are set. Pollutants

regulated in this way include nitrogen oxides, sulfur oxides, and other greenhouse gases (particularly carbon dioxide).

Just as the United States sets a standard for much of the rest of the world in terms of automobile emissions, California sets standards for the United States. California's state regulations regarding automotive emissions are stricter, on average, than most of the rest of the United States. This has the effect of raising standards so that manufacturers may sell in that affluent and highly populated state. Thus, if standards are raised in California, they are effectively raised in the rest of the United States, and, thus, the rest of the world.

The greatest problem posed to society by automobiles is pollution. The vast majority of pollution from internal combustion engines is caused by incomplete combustion of fuel. Over time, engines have become more efficient at burning fuel, but only so much energy can be derived from conventional fuels with conventional engines. After combustion, conventional engines expel waste in the form of carbon dioxide, carbon monoxide, water, particulate matter (soot), nitrogen oxides, ozone, methane, and other harmful compounds. The mass release of these compounds by hundreds of millions of cars each year worldwide has detrimental results. When exposed to these chemicals, individuals may develop asthma, lung cancer, cardiovascular ailments, and other health issues. Automotive pollutants also have detrimental effects on the environment beyond humans. This includes damage to the ozone layer, acid rain, global warming, and other negative ecosystem impacts.

The U.S. Clean Air Act is by far the most influential piece of legislation in regard to automotive pollution. This act is a federal law designed to control air pollution within the United States. It was signed into law in 1963, and it was the first major U.S. environmental law to include provisions for citizen lawsuits. Additionally, the act requires the Environmental Protection Agency to enforce regulations that protect the general public from air pollution. The Clean Air Act also regulates emissions of hydrocarbons, carbon monoxide, and nitrogen oxides as well as particulates emitted by diesel engines. The act requires major stationary sources of pollution (such as power plants) to install pollution control equipment and to meet emissions limitations set by the act. Not only the

This cross-section of an internal combustion engine shows three pistons (cylinders). The majority of automobile engines have four or six pistons, but larger vehicles often have more.

users of fuels are expected to abide by EPA regulations but also those providing fuels are expected to meet certain standards. Fuel refiners, importers, and other parties in the fuel distribution system are expected to produce fuel that will contribute to lower emissions. Additionally, the act requires operating permits for manufacturers, processors, refiners, utilities, and others; these operating permits are issued by the EPA.

Since its inception, the Clean Air Act has seen its share of adjustments and amendments. In 1970, the act was expanded beyond stationary emissions sources (such as power plants and steel mills) to include mobile emissions sources, such as automobiles. These automobile standards regulate both the composition of fuel burned in the vehicle as well as emission control components within the vehicle. These standards apply to both road and nonroad engines. The 1990 amendment to the Clean Air Act

served to implement stricter standards for multiple elements of the act; these standards were to be met by 2005.

In 2010, the Clean Air Act was expanded to regulate automobile-caused global warming. The legislation was written by the Transportation Department and the Environmental Protection Agency. With this legislation, emissions and mileage standards, which will go into effect in 2016, were further refined. Under these new standards, the average new vehicle must get at least 35.5 miles per gallon toward the goal of further reducing emissions of carbon dioxide and other heat-trapping gases. Auto makers wishing to sell vehicles in the United States are expected to comply with these regulations by 2017. These regulations are expected to add \$1,000 to the purchase price of vehicles for consumers. However, the savings in fuel are expected to result in a savings of approximately \$3,000 to the driver over the life of the car.

Automobile Financing

Many consumers who purchase a vehicle use some form of financing to cover the cost. The most common forms of borrowing to buy a vehicle are dealership financing, direct lending through a bank/credit union or online financial institution, a home equity loan, or a personal loan from a family member or friend.

Perhaps the biggest benefit of dealership financing is its speed and convenience. However, the associated rates and fees often are not market competitive, and buyers end up paying more overall for the up-front expediency and ease. Banks and credit unions, on the other hand, tend to offer more competitive rates and simpler loan structures, but they are more complex and time-consuming to obtain. Online financial institutions are similarly competitive with their rates and offer consumers more flexibility than brick-and-mortar lenders. The downside with online lending is the greater possibility of disreputable providers or outright scammers.

Home equity loans enable the consumer to deduct some of the loan interest from his or her tax filings, but this increases the overall financial burden and risks tied directly to the individual's home. Financing through a family member or friend comes with its own set of risks, mostly tied to the health of the relationship. While a personal loan from a family member or friend can seem simple and more flexible than other financing options, it could also cause anxiety and ill will that could damage an otherwise positive relationship.

Automobile Dealership Financing

When a buyer chooses a direct lending option, such as obtaining a loan directly from an automobile dealership or financial institution, the buyer uses the loaned funds to purchase the vehicle and becomes legally obligated to pay the amount lent plus a specified finance charge monthly or at another designated interval over a set period of time that typically ranges from three to six years.

Most automobile dealerships have an on-site Finance and Insurance (F&I) department that facilitates the loan process. The first step in the process is typically having the buyer complete a credit application that asks for personal information such as date of birth and Social Security number, details about

employment history and income sources, and data related to existing debt and credit accounts. The F&I representative uses this information to obtain a credit report of the buyer's previous and existing credit obligations and repayment history. The credit report provides details on each account held by the buyer, including the account number, account type and terms, account credit limit, recent balances, and payment activity. If applicable, the credit report also indicates a creditor summary of past-due information and any legal actions taken to collect payment on the accounts. Only a buyer who is seriously considering financing with the dealership should agree to have a credit report generated; each time a credit report is run, the individual's credit score can be lowered.

The credit report information is sent to the dealership's lenders—banks, finance firms, or credit unions—to determine which one offers the lowest interest rate for the specific buyer. The lender bases its rate on the buyer's credit report, completed credit application, and details about the terms of the sale, such as the amount of down payment the buyer will make. Buyers with a good credit history and established sources of income benefit from lower rates than buyers who have a history of late repayment, a previous bankruptcy, or very low or unstable income. In instances where buyers fail to qualify for vehicle financing on their own, a cosigner with favorable credit history and income may be required. The cosigner assumes equal responsibility for the contract, meaning that if the primary borrower cannot pay back the loan, the cosigner is obligated to make the payments.

The dealership's F&I representative typically takes the lowest approved interest rate for a buyer and adds an amount—often a percentage—that serves as the dealership's profit for selling the financing service to the buyer. As such, dealership financing is considered an add-on sale with terms outlined in a retail installment sales contract. Like most selling propositions, financing sales are subject to special offers and incentives from time to time. For example, an automobile dealership may offer manufacturer rebates or no-interest deals for a certain loan term. Such deals typically restrict who can qualify or which vehicle models are covered.

Sometimes automakers offer rebates to buyers; such rebates are cash given back to the buyer as an incentive to purchase a certain vehicle. These

types of offers often are used to help clear excess inventory when sales are slow for a particular vehicle model. Manufacturer rebates are separate from the dealership's financing package and can be applied—or not, at the buyer's discretion—to mitigate the cost of the down payment at the time of purchase.

Another financing-related sales tool used by automobile dealerships is 0 percent interest offers. To qualify for no APR (annual percentage rate) on financing, buyers generally must agree to stricter loan terms. For example, buyers may need to accept a shorter financing term of three years or less. The compressed loan cycle means that repayment installments will be much higher. In addition to shorter loan terms, buyers who want to take advantage of no-interest financing must meet stringent credit criteria and have a credit score of 680 or higher. The dealership offers tied to no APR often are limited to actual vehicle inventory on the lot and do not include the opportunity to special-order desired features.

In cases where a manufacturer rebate also is offered on a selected vehicle, the buyer seeking no-interest financing generally has to give up the cash rebate, and vice versa, as only one special offer typically applies. Sometimes it is more beneficial to the buyer to obtain the rebate and secure financing outside the dealership, especially since many dealerships ultimately sell their loan agreements to external financial lenders. The lenders take over the financing contract with the buyer and manage the details of loan administration.

Other Sources for Automobile Financing

Buyers also have the option of going directly to independent financial lenders for their vehicle financing. Even if the buyer decides to accept dealership financing in the end, it may be beneficial for potential purchasers to research other loan options beforehand so they can make more informed financing decisions. The logical starting point for the buyer is his or her own bank. Most banks provide preliminary information about vehicle loan rates and other loan costs to their customers in person or over the phone. If the customer wishes to proceed with obtaining a more formal quote for a vehicle loan, much of the required credit application information is already in the bank's system, which can help hasten the credit decision process.

Online financial institutions offer similar opportunities for vehicle loan information and quotes. Individuals can type their personal details and loan preferences into an online form to receive instant data and cost estimates for vehicle financing. Before entering any personal information online, buyers should be sure to confirm the organization's legitimacy through aggressive research, including calling one or more of the telephone numbers listed on the site, and to verify that the site's online forms are protected with security software and privacy policies, which are usually indicated clearly on the site. Reputable online lenders can provide very competitive vehicle financing rates.

Credit unions also offer automobile financing services, often at lower interest rates than banks or dealerships. The main catch for this type of financing is that many credit unions require loan recipients to be members of the credit union. Those who qualify for membership may be able simply to open a small checking or savings account with the credit union to be eligible for the institution's low-interest vehicle financing.

Buyers can use the information and quotes gleaned from a bank, online financial institution, or credit union to serve as a reference when considering financing through an automobile dealership program. Buyers should take detailed cost and interest-rate information from their research with them to the dealership to compare APR, loan structure and terms, associated fees and prepayment penalties, and other elements of the financing.

Homeowners have the additional option of obtaining a home equity loan. A home equity loan borrows from the home's accumulated equity—the difference between the amount owed and the amount at which the house is assessed—to provide cash that the homeowner can use to fund large purchases like major home improvements or a new automobile. Homeowners typically can deduct in their tax filings some of the interest paid on a home equity loan. Such loans also offer better rates in some cases than a straightforward vehicle purchase loan.

Automobile purchasers who discover and secure a good financing option before they visit the dealership can shop as a cash buyer, using the prearranged funding as the cash for outright purchase and repaying the external lender rather than the dealership.

Assessing Affordability

Before any buyer begins shopping for a new vehicle, he or she should determine overall affordability. Specifically, buyers need to know how much money they can afford to pay each month on a vehicle loan. Working backward from there, buyers need to perform some research to estimate anticipated loan term, financing and interest rate fees, and other associated loan costs to come up with a maximum price they can afford for vehicle purchase. Buyers should also consider any savings they intend to use as a down payment for a vehicle and whether they plan to trade in another vehicle as part of the new vehicle purchase. Knowing which assets will be applied and capping the purchase price at a manageable level prior to visiting a dealership will help buyers narrow their search and negotiate the most appropriate financing for their individual circumstances.

Key Regulations

Several federal laws are in place to help regulate automobile financing. The Equal Credit Opportunity Act bars discrimination in credit lending based on age, gender, race, religion, color, marital status, national origin, receipt of public assistance, or activation of rights under the federal Consumer Credit Protection Act. The Fair Credit Reporting Act provides consumers with the right to one free credit report annually and establishes a process by which consumers can dispute information in their credit file. The Truth in Lending Act requires that creditors provide loan applicants with written disclosure of important terms of the credit agreement such as APR, total finance charges, monthly payment amount, payment due dates, total amount being financed, length of the credit agreement, and any charges for late payment prior to the buyer signing the contract.

If a potential cosigner is part of the loan agreement, the Credit Practices Rule requires creditors to provide written notice to all cosigners about their liability for payment should the borrower fail to pay.

Broad Economic Impact

Every vehicle purchase has economic implications beyond an individual's personal finances. The automotive industry in the United States relies on vehicle sales to drive business and jobs, not just at the dealership but also at automobile design firms,

manufacturing plants, parts and accessories suppliers, maintenance and repair shops, gas stations, and other enterprises directly related to vehicle purchase and use. Indirectly, a host of other industries also rely on vehicle sales to support their success. Financing, marketing, and travel are just a few of the peripheral sectors that are greatly influenced by trends in automobile sales.

Robust vehicle sales potentially mean more business for more companies across the United States, helping maintain healthy employment levels and a strong U.S. economy overall. The reverse, however, is also true.

allowed the United States to become the largest automobile producer for much of the 20th century, although it was overtaken in this role by Japan during the 1980s. Though it is still one of the largest domestic manufacturers, the automobile industry suffered from financial problems beginning in the 1970s due to various factors. These factors included rising petroleum prices, increased competition from foreign automakers, changing consumer tastes, and an inability to deliver products that were reliable and fuel efficient. Culminating in the financial crisis of 2008, two of the United States' "Big Three" automakers needed government loans and investments to survive. The size of the automobile industry, and its importance to the U.S. economy, suggests that its financial health remains a matter of interest to many.

Early History

By the 1880s, the horse-drawn buggy provided many Americans with a reliable and consistent means of transportation. Technological developments that resulted in smaller, more efficient, and less expensive battery-powered electrical, internal combustion, and steam engines resulted in the development of a nascent automobile industry during the following decades. In the 1890s, hundreds of automobile manufacturers sprang up, although many of these built only a handful, sometimes even a single, vehicle. Ransom E. Olds was the first automobile manufacturer able to use the mass production process. Olds, who introduced his Oldsmobile in 1901, had sold over 3,700 automobiles by 1903. Other manufacturers also began to mass produce automobiles, and the industry became a major source of employment.

While many decry government subsidies for the automobile industry, it has received economic support—directly or indirectly—from the public purse almost since the beginning. In its infancy the automobile industry was severely constrained by the paucity of appropriate roads. While certain cities, towns, and villages had paved roads within their boundaries, most travel of any distance was conducted via rail or waterways. Those roads that existed between cities were mostly dirt surfaces and difficult to traverse, especially in inclement weather. To alleviate this problem, the U.S. Congress passed the Federal Aid Road Act of 1916, which provided \$75 million to build roads that were suitable for

Automobile Industry, Economics of

Developed in the 1890s, the automobile industry rapidly evolved into a major engine of the U.S. and global economies. The size of the U.S. domestic market, coupled with a wealth of natural resources,

automobiles. This act proved so popular that it was augmented by the Federal Aid Highway Act of 1921, which provided additional road construction monies. As a result of these subsidies, by 1924 the amount of paved road in the United States had increased to over 30,000 miles, creating a means and a market for automobiles to travel distances.

Olds was joined by a variety of other competitors. Henry Ford, who had begun building cars in 1896, started to manufacture automobiles under his own name in 1903. In 1913, the Ford Motor Company was the first car builder to use a conveyor belt-based assembly line, allowing it to use the economy of scale provided by mass production to lower the price of its Model T automobile, first introduced in 1908. Although originally costing \$850, the price of a Model T had declined to \$290 by 1924. This reduction in price made the Model T extremely popular, selling over 15 million units in total, and helped the Ford Motor Company grow into the United States' largest automobile manufacturer by the late 1920s.

William Durant had taken control of the Buick brand and later acquired Oldsmobile and another brand to form General Motors Corporation (GM) in 1908. After Durant was ousted from General Motors following a board coup, he founded the Chevrolet Motor Company and later retook control of the General Motors Corporation. Under Durant's successor, Alfred Sloan, General Motors grew to become the world's largest automaker. Under Sloan's leadership, General Motors came to develop highly decentralized management. Each of the corporation's divisions produced a different type of line aimed at a different segment of the auto-buying public. Chevrolets, for example, were aimed at entry-level buyers, while Cadillacs were made for high-income purchasers, with other makes, such as Pontiac, Oldsmobile, and Buick, each aimed at different demographics. To facilitate the purchase of its vehicles, GM started the General Motors Acceptance Company to help consumers finance the purchase of its automobiles. GM expanded overseas during the 1920s, purchasing the United Kingdom's Vauxhall Motors Ltd. and Germany's Adam Opel AG, which allowed it to continue to compete with Ford, which had also expanded overseas during this era.

Walter Chrysler had worked with Durant at General Motors, heading the Buick division before

resigning in 1919. Hired to lead flagging competitor Willys-Overland Motor Company in 1920, Chrysler left that manufacturer over a dispute and took over the Maxwell Motor Corporation, which he reorganized into the Chrysler Corporation shortly thereafter. Purchasing the Dodge Brothers Company in 1927, Chrysler significantly expanded production and sales during the 1920s, becoming the second-largest automobile manufacturer behind General Motors during the 1930s by introducing several other makes, including the Plymouth and the DeSoto.

Although Chrysler was innovative in introducing an aerodynamic design for its cars in 1934, this innovation was rejected, causing the company to embrace conservative styling for the next several decades. With GM and Ford, Chrysler was one of the three largest automobile manufacturers that dominated American sales, known informally as the "Big Three."

A variety of smaller automobile manufacturers were busy through the 1920s, with many targeting niche markets. The high-end luxury sector included the Duesenberg Motor Company, the Peerless Motor Company, the Pierce-Arrow Motor Car Company, the Stutz Motor Company, and others. Smaller companies were also responsible for many innovations during the 1920s: the Franklin Automobile Company experimented with air-cooled aluminum engines, and the Auburn Automobile Company introduced front-wheel drive on its Cord automobile and other innovations. Although popular with sectors of the car-buying public, most of these smaller car companies did not survive the Great Depression and ceased doing business by 1940. In addition to the Big Three, only a handful of smaller automobile manufacturers survived the Great Depression. Those companies that survived included Crosley Motors, the Hudson Motor Car Company, the Packard Car Company, Nash-Kelvinator Corporation, and the Studebaker Corporation.

The Depression saw a huge contraction of the American economy, with unemployment rates rising to as high as 25 percent. As a result of this downturn, automobile sales plummeted, and many smaller companies were unable to survive. These troubles also affected the Big Three, and unemployment rates near Detroit, Michigan, exceeded 30 percent. Low-skilled laborers were often the

first to be laid off by the automobile manufacturers. Although the automobile companies made some small attempts to assist the terminated workers and their families, for the most part they were left to their own devices. These problems, coupled with the difficult environments in which the workers had to toil, made the situation ripe for labor unions. The United Auto Workers (UAW) worked to build a membership base and was recognized by General Motors and Chrysler by 1937. Although it attempted to hold out, Ford joined its competitors in agreeing that its employees be represented by the UAW. This representation led to significant changes in employment conditions, and benefits such as pensions and medical insurance began to be offered. The cost of these benefits would later prove a difficult problem with which the automobile manufacturers had to deal.

World War II

On December 7, 1941, the Imperial Japanese Navy launched an aerial attack on the U.S. naval base at Pearl Harbor in Hawaii. As a consequence of this attack, the United States declared war on Japan the next day and thereby entered World War II. As a result of this action, all automobile manufacturers were required to participate in the war effort, which entailed manufacturing a variety of other vehicles, including tanks and aircraft, while also producing a variety of other weapons. Because of this transformation, passenger automobile manufacture was halted in February 1942. Although the manufacturing processes of the automobile companies were devoted to war-related orders, the factories and other offices were under the control of company management. In consultation with the military, the automobile manufacturers spent most of the next four years involved in wartime production.

Although the automobile manufacturers had been producing war-related orders before Pearl Harbor, the scope and scale of wartime production was staggering. Production levels of the auto manufacturers often doubled or increased at an even greater amount. Many factories were enlarged to keep up with this demand, and many new factories were constructed, all of which would be reconverted to automobile manufacture after the conclusion of the war. Hundreds of thousands of new employees were hired by the automobile manufacturers to meet the

demands of the war effort, and new manufacturing techniques were learned. Because the automobile companies were able to produce aircraft and other newly engineered products, the leaders of the industry were able to acquire a variety of improvements due to new manufacturing processes.

Postwar Production

In the year immediately following the conclusion of World War II, the automobile industry was strangely quiet, as factories were rapidly retooled for a return to domestic production. Once this process was complete, however, the pent-up demand caused by nearly five years of no new automobile production caused sales to soar. Before the war, the Big Three had controlled slightly more than 70 percent of automobile production in the United States. During the 1950s, their market share sometimes reached nearly 95 percent. This consolidation furthered the influence that the Big Three exerted over the industry. Other factors that influenced the success of the automobile industry during the 1950s included labor unrest, the burgeoning civil rights movement, and fierce competition for customer loyalty.

Returning servicemen helped build the market for automobile sales. During the 1950s, nearly 60 million automobiles were sold in the United States, amounting to one vehicle for every three individuals. Reflecting the overall prosperity being experienced by the United States, American-built automobiles became larger and more powerful in the postwar era. The V8 engine, which had been introduced to the general market during the 1930s by Ford, proved very successful with consumers. An internal combustion engine with its cylinders and pistons aligned in a V shape, the V8 engine employs 8 pistons to drive a common crankshaft.

Because the V8 could fit in the same engine compartment as a V6 engine, automobile dealers were able to increase their profits by selling the larger engine as an upgrade to the standard model. Coupled with a strong advertising campaign, the V8 was popularized in film and song, and demand for the engines soared. GM introduced a V8 engine in its Oldsmobile and Cadillac models in 1949, and Chrysler introduced its own Hemi-head V8 in 1951. For the better part of the next three decades, car companies fed consumers' interest in power by building ever larger V8 engines.

The popularity of larger size demonstrated by the soaring sales of V8 engines was mirrored in growing automobile bodies. Cars became longer, lower, and wider as increasingly powerful engines could easily power the greater load. Reflecting the prosperity most workers were enjoying, automobiles became more expensive and luxurious during this decade as well. In keeping with the fascination with the space race between the United States and the Soviet Union during the 1950s, cars began to more closely resemble airplanes. Rear fins appeared on many automobiles and grew ever larger as the decade progressed. Bumpers, lights, and chrome decoration all appeared on automobiles during this decade.

Automakers began to offer rapidly changing features and innovations, introducing a new feature and then retiring it after several years. This practice, known as planned obsolescence, appealed to consumers' interest in new and convenient features that promised to make their ride more comfortable. Because the features and designs changed rapidly and regularly, however, cars appeared dated within only a few years so consumers were often eager to trade in their vehicles for new models. Some features focused upon safety while others, such as the rear fins, appealed only to a sense of style. But this constant and continual changing of design helped build consumer desire for new cars, creating an economic model that depended upon frequent purchases of new vehicles. This economic model led American automakers to focus upon cosmetic appearance and innovative features rather than upon durability or dependability of the automobiles produced.

Certain features, such as automatic transmissions and power steering, made automobiles easier to drive and were highly appealing to many consumers. As automobiles grew increasingly larger, automatic transmissions and power steering made them easier to operate. Although the automatic transmission had been developed during the 1930s and first introduced on a 1940 Oldsmobile, the advent of World War II had prevented it from being heavily marketed until the postwar era.

The automatic transmission changes the gear ratios of the automobile as the vehicle moves with no action necessary by the driver. This differs from a manual transmission, which requires a driver to shift the gears manually while driving. Used on

tanks during the war, automatic transmissions were trumpeted by GM as being "battle tested" when they again became available during the 1950s.

Since the automatic transmission makes a vehicle easier to drive, it was marketed to consumers for two primary reasons. For one, the automatic transmission permitted the driver to concentrate more fully on navigating the vehicle, so it was seen as enhancing the safety of a trip by preventing distractions that would otherwise divert his or her attention. In addition, the automatic transmission made the vehicle easier to drive, as it eliminated the need to learn how to operate a manual transmission. As the automobile companies were trying to appeal to as many buyers as possible, the chance that a vehicle could be used by other than experienced drivers was often persuasive as this increased the potential market for the automobile that included the option or options that made it more accessible.

The decision to pursue customers who desired ever-changing features and innovative and changing designs began the strategy known as "planned obsolescence," whereby automobiles were designed to have a limited useful life span after which they became unfashionable and needed to be replaced with a new model. The practice of introducing new automobile models annually is part of this strategy, which initially proved highly profitable for American automakers but which would eventually have negative repercussions that affected their economic health.

Power steering was another innovation that appealed to drivers for multiple reasons. Because power steering augments the driver's efforts in turning the steering wheel by providing hydraulic support, it requires only slight effort to turn the wheel and makes it much easier to turn the steering wheel even when a vehicle is moving slowly or stopped. First available on the 1951 Chrysler Imperial, power steering was soon adopted by GM's Cadillac. Power steering initially added about \$200 to the price of a new vehicle, which increased the manufacturer's profits and increased the motivation to include it on automobiles. Power brakes, which use a vacuum booster to multiply the effort the driver exerts while stopping the car, also were first introduced as an option during the 1950s, with upscale makes such as Buick, Mercury, and Edsel (Ford) making these available to consumers for an upgrade in cost. Again, the option provided convenience and ease

A worker assembling an automobile hood in the General Motors (GM) Fairfax Assembly Plant in Kansas City, Kansas, in August 2012. Spurred by the near collapse of U.S. automakers GM and Chrysler after the financial crisis that began in 2008, the U.S. government invested more than \$62 billion in the two companies, as well as \$18 billion in GMAC and Chrysler Financial.

for the driver while also appealing to many consumers' desire for safety. As an option, it permitted manufacturers to increase profits while also underwriting the development of new features.

Some options, such as air conditioning and in-car radios, were marketed purely as a luxury experience while others, such as seat belts, appealed only to those concerned with safety. Automobile air conditioning, which could cool air and eliminate humidity from the passenger compartment of a car, was especially popular in the south. Though a number of companies had experimented with automobile air conditioning before the war, in 1953 Chrysler sold the first vehicles offering this as an option. A decade after it was introduced, nearly 25 percent of cars sold in the United States contained air conditioning.

Radios had long been available in automobiles, but because they utilized vacuum tubes that often broke, they were frequently out of service. By the mid-1950s Chrysler first offered an all-transistor radio as an option. More reliable than tube radios, the option became popular, unlike a miniature in-car phonograph that Chrysler introduced about the same time. Seat belts, also first offered as an option during the 1950s, were initially not very popular with drivers. These became standard equipment only after legislation made them required on all vehicles.

During the 1960s the federal Interstate Highway System, begun in 1955, was beginning to increase the demand for automobile travel. This, coupled with the growth of suburban areas, increased the need for automobiles. The Interstate Highway

System was highly popular with, and heavily supported by, executives in charge of the American automakers. There were two reasons for this support. First, increasing the number of highways also increased the market for automobiles, thus creating an ever expanding market for the automobile companies. Second, because the costs of the Interstate Highway System were borne by the taxpayers, this gave those who chose to travel by automobile a cost savings compared to railway travel, which required the railroads to build and maintain their own tracks, which increased the price of tickets.

Families began to purchase a second automobile, something that seldom occurred even a decade before. For this reason, a market developed for smaller automobiles. To support this market, and to compete with compact imported cars that were beginning to appear, the Big Three began developing smaller models. Ford debuted the Falcon during this decade, and Chevrolet introduced the Corvair, and Plymouth the Valiant. These cars were less successful than a group of sporty cars that became popular, beginning with Ford's Mustang, introduced in 1964. Automobiles of this class, known as "pony cars," were popular and the Mustang spawned a host of similar models, including the Chevrolet Camaro and the Dodge Challenger. "Muscle cars" also became popular during this decade, models that combined a powerful engine with a mid-sized body. Popular models included the Pontiac GTO, the Dodge Charger, and the Ford Torino. Although these cars remained popular throughout the late 1960s, high insurance rates on these automobiles greatly diminished their popularity after a few years.

Government regulations, which had not occurred with much frequency before the 1960s, also became more common during this decade. Public concerns regarding safety and environmental protection caused the development of a regulatory system with which the automobile industry had to comply. Beginning in 1962, many states began demanding that new vehicles contain seat belts, which originally were lap belts. After studies suggested these lap belts could cause injuries under certain circumstances, the National Traffic and Motor Vehicle Safety Act of 1966 set standards intended to protect public safety. The changes demanded by these standards were many. Beginning in 1968, front-seat passengers needed to be

provided three-point seat belts, front-seat headrests became mandatory, steering columns had to meet energy-absorbing criteria, interior features such as dashboards required padding, ignition key warning systems needed to be installed, and marker lights needed to appear on the sides of vehicles.

These safety regulations were enacted concurrently with a variety of laws and regulations intended to protect the environment. After the U.S. Congress passed the Clean Air Act of 1963 and the Vehicle Air Pollution and Control Act of 1965, auto emissions became regulated for the first time. Beginning in 1968, emission controls began to be used, and leaded gasoline began to be phased out during the early 1970s. Newer vehicles needed to comply with the mandate to use unleaded gasoline, which resulted in the use of lower compression engines. The lower-compression engines resulted in lower horsepower and performance, which removed two areas of strength for American carmakers in their battle against imported automobiles. By the end of the decade, new automobiles required catalytic converters, which further impeded performance. By the mid-1970s, the era of dominance by the Big Three was over.

Labor Issues

The automobile industry was not completely unionized until Ford recognized the United Automobile Workers (UAW) in 1941, following Chrysler and GM, which had done so in 1937. Founded in 1935, the UAW was able to organize quickly and use the sit-down strike to gain concessions from the automakers. Walter Reuther, the longtime head of the UAW, was a socialist who fought for social changes above and beyond contract matters. The UAW was among the first labor unions that accepted African American members. Reuther developed the UAW into a disciplined and responsible organization that was able to gain tremendous concessions from the automobile manufacturers, concessions that later negatively affected their economic well-being.

During World War II, the UAW's rank and file made a "no strike" pledge, a move designed to ensure that the war effort would be able to proceed at full force. This no strike pledge ensured that strikes would not interfere with the production of weapons, aircraft, tanks, and other needed material. Immediately after the conclusion of the war,

however, the UAW again began using the strike as a bargaining tool. In negotiations with GM, Reuther sought a greater voice in management decisions for workers, a position that GM resoundingly opposed. To that end, Reuther led the UAW workers in a 113-day strike against GM, although he was ultimately unsuccessful in his efforts to get GM to agree to power sharing. The UAW was able to extract an 18-cent-per-hour rise in wages. This increase, although large at the time, did not satisfy the more radical members of the UAW, who then sought implementation of a 30/40 scheme: a 30-hour workweek compensated by 40 hours of pay. Reuther rejected the push for 30/40 and instead concentrated on gaining paid vacations for members and increased annual pay. As this was obtained, the UAW next sought additional increases in benefits, such as pensions and medical health care insurance.

The high level of competition between the Big Three during the 1940s and 1950s permitted the UAW to exert economic pressure on the auto manufacturers in order to gain the concessions it sought. After the UAW's executive board decided upon the next goal for its membership, Reuther selected one of the Big Three and demanded this concession in its next contract. If the automaker refused, the UAW members at that company went on strike, effectively shutting it down while its two competitors divided its market share. Once the original target capitulated, the UAW then demanded the same concession from the other two carmakers, which capitulated rather than go through the same process.

In 1950, the UAW negotiated a contract with GM that would shape labor relations within the automobile industry for decades to come. At that time, Reuther negotiated a five-year contract that came to be known as the "Treaty of Detroit." According to the contract, the UAW members pledged not to strike during the five-year duration of the agreement, which provided the automakers with increased security. In exchange, Reuther extracted a wage and benefits package that was considered staggering at the time. GM workers were provided with extensive health and pension benefits, increased wages, increased vacation time, cost of living adjustments to wages, and supplemental unemployment payments in the event of a layoff. This wage and benefit package was soon adopted by Chrysler and Ford, and many of the Big

Three's smaller suppliers also adopted these benefits for their employees.

While the Treaty of Detroit provided American autoworkers with one of the highest standards of living in the world during the 1950s and 1960s, it later came to represent an economic burden on the automakers and even on the UAW membership. By the mid-1970s, competition from European and Japanese carmakers had increased significantly. Because many other nations provided pensions and health care via national programs, the pension and health benefits provided by the Treaty of Detroit placed the Big Three at a competitive disadvantage with regard to the other manufacturers. As a result, when the Big Three built new plants, they often chose to do so outside the United States, as this would save them the cost of pensions and benefits. These cutbacks greatly affected the membership of the UAW, which had been more than 1.5 million members in 1979, but which had fallen to approximately 380,000 active members by 2013.

Oil Embargo to the Present

Beginning in 1973, the Organization of Petroleum Exporting Countries (OPEC) declared an oil embargo against the United States due to opposition to U.S. foreign policy in the Middle East. As a result of this action, the price per gallon of gasoline soared, and larger American-made cars and trucks were suddenly at a competitive disadvantage compared to smaller, fuel-efficient imported automobiles. In an effort to spur more efficient automobiles, the U.S. government mandated that the miles per gallon (mpg) of cars in an automaker's fleet average 18 mpg by 1978, rising to over 27 mpg by 1985. This caused the Big Three to take radical action, with GM downsizing its entire model line in 1977 and with all manufacturers introducing smaller, more fuel-efficient cars.

Unfortunately, the speed with which the Big Three adopted these changes resulted in a sudden and considerable decline in quality control and customer satisfaction. As a result, the Big Three's market share declined precipitously at a time when it also was required to devote more revenues to the research and development of new models. Increased foreign competition made it necessary for American automobile companies to offer incentives to encourage consumers to purchase their products.

These incentives included “rebates,” which amounted to cash refunds issued to those who purchased new cars and below-market interest rates offered through finance companies controlled by the automakers, such as General Motors Assurance Corporation (GMAC), Chrysler Credit Corporation, and Ford Motor Credit Company (Ford Credit). Although these plans increased sales, they damaged the automakers’ profitability and proved impossible to sustain over time.

The Big Three’s troubles benefited many foreign automobile manufacturers but especially the Japanese. Toyota Motor Corporation, Honda Motor Company, Nissan Motor Company (Datsun), and others saw their sales soar. During the 1980s the market share of foreign automakers grew rapidly and further hurt the sales and image of the Big Three. In response, GM, Chrysler, and Ford sought to increase their expertise, which resulted in investments by the American automakers in Isuzu Motors Ltd., the Mitsubishi Group, and Mazda Motor Corporation, respectively. These investments resulted in a variety of new models, some made overseas but branded with American nameplates. After the price of oil declined by the mid-1980s, the fortunes of the Big Three revived. Chrysler introduced its hugely successful minivan, Ford enjoyed critical success with its revitalized aerodynamic styling, and GM invested in new technology designed to lower the costs of production.

During the 1990s, the spike in oil prices caused by the Gulf War weakened automobile sales and resulted in temporary operating losses, although the Big Three had again rebounded by mid-decade. As fuel prices declined, the sales of large sport utility vehicles (SUVs) and light trucks soared. As SUVs and trucks are among the most profitable of models for the Big Three, all three did well during the decade. In 1998, German carmaker Daimler-Benz AG purchased Chrysler, a “merger of equals” that ultimately proved unsuccessful and resulted in Chrysler being spun off to a private equity firm in 2007.

Although GM began experimenting with the EV1, an electric-powered car that it offered for lease to the public from 1996 until 1999, followed by the Gen II successor vehicle, the program was ultimately canceled in 2003 due to slow sales. This decision, especially following billions of dollars of investment in the program, was to prove harmful not only to GM but also to the American auto industry as a whole.

While automobile sales rebounded quickly after the 2001 recession, the stock prices of the Big Three lagged as fears about unfunded pension liabilities drove down the value of the manufacturers, which in turn required significant additional contributions to the pension funds with monies that were sometimes borrowed. Once fuel prices began gradually rising in 2005, sales again were negatively impacted. To counter this, all of the Big Three began depending more upon their subsidiary businesses to generate profits to offset losses in auto manufacture. As a result, for example, GMAC was to enter the home mortgage market, a decision that later proved unwise.

During the economic crisis of 2008 the Big Three, already in weakened condition, saw sales decline precipitously. In November 2008, the chief executive officers (CEOs) of the Big Three flew to Washington, D.C., to request government aid from Congress, a request that was denied. By December, President George W. Bush provided GM and Chrysler with \$17.4 billion from the Troubled Asset Relief Program (TARP). Ford, which had raised \$23 billion in cash in 2006, did not receive any funds from TARP. By spring 2009, both GM and Chrysler filed for Chapter 11 bankruptcy protection, causing President Barack Obama to form the Presidential Task Force on the Auto Industry to decide how best to support these failing companies, if at all.

After determining that GM and Chrysler were “too big to fail” because of their importance to the U.S. economy, the United States government provided a significant bailout to the automakers to ensure their continued operation. Billions of dollars in shareholder equity were wiped out as a result of this takeover. Once operated by government appointees, both GM and Chrysler engaged in many cuts, such as closing production factories, closing hundreds of dealerships across the nation, and eliminating thousands of jobs.

The revitalized companies also asked for, and received, numerous concessions from the UAW, permitting them to lower the cost of production significantly. GM shut down its Pontiac, Hummer, and Saturn brands and sold its Saab division. Chrysler was given new management from Italian automaker Fiat SpA, which also received an ownership stake in the carmaker. In total, the U.S. government invested over \$62 billion in GM and

Chrysler, in addition to an additional \$18 billion given to GMAC and Chrysler Financial. Operating on a smaller scale, GM, Chrysler, and Ford began enjoying increased sales and financially better footing by 2014.

began in the Northeast. Connecticut adopted a law in 1925, when automobile ownership was first becoming popular, requiring any vehicle owner involved in an accident to provide proof of financial responsibility in order to be allowed to continue driving. That same year Massachusetts refined this to a requirement to purchase liability insurance as a precondition of registering an automobile in the state. For 30 years, however, it was the only state to require insurance, until New York made insurance compulsory in 1956, followed by a wave of most other states.

Terminology may vary from provider to provider, but various forms of coverage include coverage for physical damage to the vehicle in the event of a collision, damage to the vehicle from some other cause (such as fire or flood), theft of the vehicle, maintenance and repairs to the vehicle, the cost of renting a car during the period when the damaged insured vehicle is being repaired, the cost of towing the vehicle to a mechanic to be repaired, damage to other vehicles in a collision, damage to property caused by the collision or by the vehicle, injury to the insured party, injury to parties in the other vehicles in a collision, and injury to passengers in the insured automobile. Typically, the insured party is required to pay a deductible in the amount determined by the insurance policy. The insurance company pays the costs in excess of the deductible amount, based on the specific damages and benefits covered by the insured's policy, up to a predetermined maximum.

Nearly every state requires that every vehicle owner carry a certain level of liability insurance, which covers the damage done to other vehicles in the event of a collision for which the driver is at fault, and often covers property damage incurred by the insured driver. A small number of states permit vehicle owners to opt out by paying an alternative fee that partially offsets the cost of uninsured drivers' involvement in accidents in the aggregate. More commonly, states require greater insurance coverage. In states that require insurance, proof of insurance is expected to be kept in the car at all times. In many states, cars that are financed through car loans from a bank or other lending institution require a greater level of insurance to ensure that the bank will be able to reclaim the value of its loan in the event the car is damaged or destroyed.

Automobile Insurance

Automobile insurance provides insurance against the costs of automobile accidents, theft, or damage from other causes. Various forms of coverage are available, and the level of insurance required of a driver or vehicle owner varies from state to state. The legal framework establishing financial responsibility in the event of vehicle accidents

Collision coverage is the most basic form of insurance coverage beyond liability, and it provides coverage for accidental collisions. Though it is a common form of insurance because of its practical benefits to the owner, it is not commonly required by states unless the car is financed. Comprehensive insurance, which is rarely required even for financed cars, provides coverage for damage caused by events other than collision, including weather damage, fires, vandalism, and “acts of God,” which are understood to be disasters without human agency. Uninsured or underinsured motorist coverage provides coverage to the insured if he/she is in a collision in which the other party is at fault but either lacks the insurance coverage to pay the insured party’s bills or is insufficiently insured. Although liability insurance is required, it is common in much of the country for a percentage of drivers to cancel their liability insurance policies after registering their car, and so collisions with uninsured drivers occur with nontrivial frequency.

Uninsured motorist coverage is required by some states. Nearly half of the states limit the damages that can be paid by uninsured motorist coverage.

The insurance requirement is usually enforced by requiring proof of insurance to be provided when a car is registered and at its periodic safety or emissions inspection, if applicable. Some states require proof of liability insurance before a driver’s license will be issued. California and New Jersey provide additional incentive to purchase insurance by permitting only insured drivers to pursue claims for pain and suffering from injuries sustained while driving.

In addition to the insurance requirement in so many states, car rental agencies have various policies. Some will only rent to drivers who are already insured. Others may allow uninsured drivers to purchase insurance from the rental agency for the duration of the rental period. Others may require a minimum level of insurance greater than the minimum required by the state. Still others

Drivers wait for assistance after a minor automobile collision in Tokyo, Japan. Insurance coverage became compulsory for drivers in most U.S. states in the mid-1950s. Today, nearly every state requires liability insurance, which covers the damage done to other vehicles in the event of a collision for which the driver is at fault, and often covers property damage incurred by the insured driver.

impose requirements that differ based on the age of the driver. Most rental agencies, for instance, will not rent to drivers younger than 21 because of restrictions imposed on them by their own insurance policies. In some states they do not rent to drivers under age 25, and even where they do, this is often not widely publicized—drivers under 25 can usually rent only by paying a significant extra fee. For instance, Advantage, Avis, Budget, Dollar, Enterprise, Hertz, National, and Thrifty now allow drivers aged 21–24 to rent a car in states that permit them to do so for an additional fee of an average of \$25 per day, depending on the vehicle class being rented.

There are exceptions to those general rules. New York and Michigan require that all drivers over 17 be eligible to rent automobiles, though they place no limit on the extra fee that can be charged to them, which in both cases is higher than the fee charged to people aged 21–24 in most other states. Military and federal government officials 18 and older renting a vehicle while on business, and drivers 18 and older insured by USAA (United Services Automobile Association, which provides insurance to military personnel and their families) are exempt from age restrictions. Age restrictions may also be bypassed as part of a corporate contract with a rental agency, which provides the same rental rate for all employees renting under the terms of that contract (for renting a car while on a business trip).

Insurance premiums—the amount the insured pays in order to maintain his insurance policy in force—are based both on the types of coverage provided and on statistical actuarial data that bear on the probability of an insurance payout. That is, those drivers and vehicles that are statistically more likely to be involved in collisions, thefts, and other payout events are charged higher premiums. Factors impacting the premium include driver profile data including age, gender, and especially driving history, and vehicle data including the safety of the vehicle, how much it is driven, and the purposes for which it is driven. Factors that result in lower premiums are sometimes touted as discounts. For instance, drivers who can show that their insured vehicle is used for only a limited amount of driving each year may qualify, under some insurers' terms, for a discount on insurance for that vehicle.

Driving history is a major factor in determining a driver's insurance premium. The premium

will be higher if a driver's driving record includes violations such as speeding, illegal passing, and failing to abide by a stop sign, red light, or other traffic signal, as well as more serious misdemeanor- or felony-level crimes. Statistically, such violations indicate a pattern of behavior and are associated with a greater risk of accidents.

Accidents also greatly influence the amount of the premium, both directly and indirectly, in the form of removing factors such as safe driver discounts. Frequent accidents may even result in the insurer refusing to provide coverage, though more often the premium will simply be raised to a much higher level.

In most states and under most insurers, liability insurance only covers claims made against the policyholder, a driver specifically listed in the policy, or a driver of the policyholder's vehicle who is not specifically excluded by the policy and who does not live at the policyholder's address. The reason for this last requirement is to avoid skewing the liability premium by insuring vehicles used in common by members of a household under the name of the "cheapest" driver—that is, the driver whose demographic profile and driving record will lead to the lowest premiums. Given that women are typically offered lower premiums than men, and that young and inexperienced drivers are charged higher premiums than adult drivers with years of experience, this would not be a rare occurrence, and the proviso makes certain that the insurance policy of a household with teenage drivers will correctly reflect the associated risks. Because the cost of insurance is carried by every policyholder—that is, every policyholder's premiums generate the revenue the insurer needs to draw from in order to pay claims—it is in every policyholder's interest for premiums to accurately reflect risks.

Twelve states and several Canadian provinces require insurance providers to offer no-fault insurance. Kentucky, New Jersey, and Pennsylvania allow policyholders to choose between no-fault insurance and a traditional tort regime. No-fault insurance is insurance that reimburses the policyholder with no consideration of fault but places restrictions on the policyholder's right to sue other parties for damage resulting from the accident. No-fault regimes take a different view of accidents and risk than the traditional regime does, since being at fault for an accident does not increase a

driver's premiums. No-fault policies also may be seen as more practical in areas with large numbers of uninsured drivers. Florida, Michigan, New Jersey, New York, and Pennsylvania all limit the kinds of losses that can be used as the basis of a lawsuit (that is, that permit a tort), a limit that usually consists of death and permanent disability. Hawaii, Kansas, Kentucky, Massachusetts, Minnesota, North Dakota, and Utah all place a monetary limit on the damages that can be awarded (ranging from \$1,000 in Kansas to \$5,000 in Hawaii). The number of states with no-fault laws, most of which were enacted in the 1970s, used to be higher, but many states have repealed these laws.

Because many uninsured drivers never pay for the damage they cause in accidents, insured drivers pay a considerable amount of money. About one in seven drivers is uninsured (due to an increase since the 2008 financial crisis), according to the Insurance Research Council, usually because they can't afford insurance. In most cases, uninsured drivers lack sufficient assets to cover the costs of serious accidents. The most recent data on the cost of uninsured motorists comes from a 2007 study by the National Association of Insurance Commissioners, which said the cost in 2007 came to \$10.8 billion. This amount can be assumed to have increased with the increase in the number of uninsured drivers.

Automobile Manufacturing and Sales

Automobiles developed from several sources. Advances in bicycles and tricycles were coupled with engines to produce four-wheeled cars. In some cases, steam was used. The Stanley Motor Carriage Company (American) manufactured steam engine vehicles, popularly known as "Stanley Steamers," from 1902 to 1924. The light wooden frame of the car was carried on four bicycle wheels and propelled by a steam engine heated by its kerosene-fed boiler. Steam engine cars included the White Steamer (White Motor Car), the Alena Steamer (Alena Steam Products Company), Davis Steam Car, and Coats Steam Car, as well as others.

Electric cars were manufactured in Europe in the 1800s. In the late 1800s Americans began to develop electric cars. The Electric Carriage and Wagon Company of Philadelphia manufactured a fleet of taxicabs for New York City. The Woods Motor Vehicle Company of Chicago produced the 1902 Phaeton electric car, which outsold other types of cars. However, even the advances in electric battery technology, the lack of smell associated with gasoline cars, the lack of a need to shift gears, and the safety of not having to use a crank to start its engine were not enough to save the electric car from gasoline competitors after peak production in 1916.

In 1860 Etienne Lenoir built the first internal combustion engine. In the 1880s Gottlieb Daimler and Carl Benz independently developed their own internal combustion engines. In 1885 Benz built the first gasoline-powered car. Made of bicycle parts, it attained speeds of 12 miles per hour (20 kilometers/hour). Others began to manufacture "horseless carriages." The Panhard Levassor car (1891) was manufactured with many of the design principles still used in automobiles, including a front-end engine, a gearbox, foot-operated clutch, rear-wheel drive, and a radiator to cool the engine-cooling water. Others in the 1890s in Europe who built automobiles included Peugeot, Renault, Daimler, Benz, and Fiat.

In 1896 Henry Ford produced the quadricycle. Earlier in his career he had worked with Westinghouse, servicing their steam engines. At this time he was chief engineer for the Edison Illuminating Company. With Edison's encouragement, he began to manufacture gasoline-driven automobiles.

In 1899 Ford founded the Detroit Automobile Company (DAC), but because its cars were poor quality and expensive, he dissolved it in 1901 at a substantial financial loss. In 1903 he founded, with others, the Ford Motor Company. In October 1908 he introduced the Model T, with its steering wheel on the left. Simple to drive and using a manufacturing innovation, the assembly line, Ford mass-produced Model Ts at prices working people could afford. From a price of \$825 in 1908, the price fell to \$360 as production volume increased.

Using an assembly line, Ford eliminated the problems of expensive craftsman-made cars that varied in quality. Instead, every Ford car was the same with standard interchangeable parts that were assembled at a standard labor cost. In 1909 over 118,000 Model Ts were manufactured. By the 1920s a majority of Americans were able to drive the basic Model T. His combination of high efficiency and high wages were adopted by many others as “Fordism.”

The impact of an ever-increasing number of automobiles required road and bridge improvement. The traffic light, invented by Garrett Morgan of Ohio, aided the flow of traffic. In addition, service stations, parts and tires supplies, road maps, motels, and many other aids to automobile travel were created and placed in reach of the automobile market. In addition, trucks—“automobiles” for freight—were soon filling the growing road system.

Hundreds of car companies were founded and most soon folded in the early history of automobile manufacturing. The United States soon became the automobile manufacturing center of the world, a title it would hold until the 1980s when first Japan and later China would take the leads in production. By the end of the 1920s three large automobile companies dominated the industry. These were Chrysler, Ford, and General Motors (GM), which were known as the “Big Three.” General Motors made Chevrolet, Pontiac, Buick, Cadillac, and other brands. In addition, other companies such as the Hudson Motor Company (reorganized as American Motor Company in 1954), Studebaker Company, Nash Motors (Nash-Kelvinator Corporation), Crosley Motors, and the Packard Motor Car Company also contributed to the supply of automobiles available to Americans.

During the Great Depression car sales dropped dramatically. Many luxury car companies, including the Stutz Motor Car Company, Pierce-Arrow

Luxury automobiles on display at a Mercedes-Benz dealership in Munich, Germany, in 2013. Despite widespread financial crises starting in 2008, by 2010 it was estimated that there were more than a billion vehicles worldwide—double the number in 1986.

Motor Car Company, Peerless Motor Company, Cunningham, and the Marmon Motor Car Company, were forced out of business. Ford reopened for production as sales of automobiles slowly increased between 1931 and 1941 from over 1 million to over 3 million. The companies that survived the Great Depression were pressed to supply the government with vehicles during World War II. After the war ended in 1945, their assembly lines began supplying the pent-up demand for automobiles in America and around the world. From 1945 to after 1965 they dominated the global automobile market. Sales in 1950 were over 5 million out of a total 6.25 million manufactured worldwide.

Beginning in the late 1950s, foreign automobiles began to enter the U.S. market as gasoline prices were increasing. The Volkswagen Beetle became a high-selling automobile. Italian-, French-, and British-made cars also appeared on U.S. streets and highways. Yearly sales of American cars rose steadily to a peak of over 11 million in 1973 when the Arab

oil crisis seriously affected sales, which dropped to only 8 million plus vehicles. Two years later, sales again rose to over 10 million until 1980 when sales dropped again.

Sales of US cars and trucks generally had been handled by either a private dealership that held a franchise to sell the automaker's vehicles or a dealership that was a subsidiary owned by the automaker company. Often the dealers contracted with the automakers to sell their vehicles. The dealerships provided not only vehicles to buyers but also service for maintenance and repairs.

Financing automobile dealerships requires significant sums of money for the physical location of the dealership, its employees, its service department, and its inventory of new cars and trucks. Different ways of financing dealership operations have been used over the years, ranging from the automaker supplying funds, the dealer using the franchise's funds, or the dealer using loans supplied by outside investors. Inventory is often used as security for the loan.

After the cost of purchasing a home, an automobile is usually the second-largest purchase for most consumers. Some people are able to pay cash to buy a new or used car or truck. Others have to borrow in order to buy the vehicle. Many buyers can borrow directly from a finance company, bank, credit union, or other lending institution. Most dealerships have their own loan department where "dealership financing" may be arranged. The buyer and the dealer agree to the terms of the sale plus the interest cost of the loan. This system is convenient and has worked well for decades. Once the deal is made, the dealer may keep the loan and collect the monthly payments of principal and interest, but it is common for the loan to be sold to a finance company.

The latter part of the 1970s were years of significant inflation. Increasing costs and inattention to quality in favor of quantity of production caused many Americans to feel that their complaints were not being heard by the Big Three and their "rattletraps" produced with little care for consistent quality. Disenchanted with American automakers, consumers turned to Japanese-manufactured cars made by Toyota, Honda, Mazda, Isuzu, and others. Following the virtually complete destruction of their industry in World War II, the Japanese rebuilt it with careful attention to quality control. Influenced by American quality control experts, such as

W. Edwards Deming, Joseph Juran and others who were largely ignored in the United States, the Japanese produced high-quality reliable cars that were reasonably priced.

In 1947 Deming, a very skilled statistician, left the Bureau of the Census to begin working for the Supreme Command for the Allied Powers in order to prepare for the 1951 Japanese census. By 1951 he had met many important Japanese leaders and was becoming versed in Japanese culture. Among those he met were Lord Kaoru Ishikawa (who developed the Ishikawa, or Fishbone, Diagram) and a group composed of the presidents of Japan's leading industries. They soon adopted the philosophy of quality as a permanent feature of Japanese production. In 1980 the American automotive industry and other American manufacturers discovered Deming and the quality control philosophy. The discovery came when NBC broadcast a television documentary program, "If Japan Can ...Why Can't We?" The Total Quality Management (TQM) movement was launched soon thereafter. The new slogan at Ford Motor Company became "Quality Is Job 1." Japanese innovation was greater than manufacturing efficiencies. Daihatsu attracted new car buyers with its lifetime extended warranty program. Korean automobile makers also entered the U.S. market and began to make themselves major challengers to American car manufacturers.

American union contracts from 1937 onward made U.S. manufacturing costs greater than those of many foreign manufacturers. A combination of high oil prices and increasing foreign competition seriously affected American automobile companies. While they were able to recover some during the 1990s and into the mid-2000s, the financial crisis of 2008 severely impacted the Big Three. Ford continued to operate, but GM and Chrysler filed for bankruptcy in order to reorganize. Reducing the cost of labor contracts was part of the reorganization and recovery. The companies that emerged were downsized, and some cars, such as the Oldsmobile, met their end.

American car sales had risen again in the later 1980s to over 10 million units and thereafter remained steady at around 8 million units per year. From 1980 until 2012, U.S. car manufacturing declined from being the dominant global producer to a smaller global market share. China is now the world's leading car manufacturer, the United States

is second, and Japan is third; European, Brazilian, and Indian sales compose significant portions of total sales.

Automobiles continue to be driven in ever-increasing numbers around the world. It was estimated in 2010 that the world number of automobiles was over a billion vehicles. This was double the number of vehicles in 1986. Much of the increase represents automobiles manufactured in China and India. Hybrid gasoline-electrical cars such as the Toyota Prius are selling well, while newer biofuel, hydrogen-powered, and electric cars are being developed.

By the end of 2013 China was quietly buying real estate in order to open Chinese automobile manufacturing facilities in Detroit. With real estate cheap and with an abundance of unemployed skilled automobile workers and engineers in the area, the investment opportunities looked very good. The Chinese and other foreign investors in the U.S. automobile industry were aided by the financial troubles of the Big Three.

The financial crisis of 2008 adversely affected the Big Three automobile companies in Detroit. Historically, money had been borrowed in order to finance automobile manufacture and sales. However, the money was suddenly unavailable so, in order to avoid bankruptcy, they turned to the federal government. They were able to secure \$50 billion in guaranteed loans as a bailout. Critics denounced the move, but supporters of the loans said that three million or more workers would be unemployed in a short time if the bailout loans were not made.

The Barack Obama administration, which took office in January 2009, used \$24.9 billion from the Troubled Asset Relief Program (TARP) to create the Automotive Finance Program to make loans to the automakers so that they could lend to car buyers. In order to get the bailout, the automobile companies agreed to consolidate operations and also to move toward the rapid development of energy-efficient trucks and cars. Also included in the bailout terms were delays in contributing to the health insurance and retirement benefits of both retirees and current workers. Ford Motor Company did not need the loans; however, it took the bailout money in order to stay competitive. By 2013 all of the automobile bailout loans had been repaid with interest.

Automobile Operating Costs

Automobile operation involves both direct and indirect, internal and external costs. Direct costs include (depreciated) vehicle purchase or leasing costs, insurance, registration, fuel, maintenance, parking, tolls, and costs associated with time lost from congestion and personal or property damage from crashes. Indirect costs are much less apparent to drivers but can represent 30 percent or more of total vehicle operating (plus ownership) costs. They include external accident costs (such as government-paid medical costs, police response costs, and the lost economic activity of those delayed by accidents), local road construction and maintenance costs, employer-paid or tax-supported parking, air pollution damages, road noise, congestion costs, greenhouse gas emissions, water pollution, and others. Direct costs are those borne by the travelers themselves or those who provide the vehicles, fuel, and roadways, while indirect costs are borne by others, who do not make the decision to manufacture or use the vehicle imposing the costs. Many

of these costs (even the relatively direct costs) are hidden from drivers when they decide whether or not to use their automobiles for a trip.

Americans spend nearly 20 percent of their household budgets on vehicle expenses, including 9 percent on vehicle purchases, 3 percent on gasoline and motor oil, 1 percent to finance the vehicle, over 2 percent on insurance, and nearly 3 percent on maintenance, repairs, and other charges. For the average U.S. household in 2002, these costs made up \$7,371 on average.

Depreciation makes up nearly half the costs of new-vehicle ownership, over the first five years. Fuel costs make up 24 percent, followed by interest payments at 11 percent, insurance at 10 percent, and maintenance, repair, and taxes at about 8 percent. Vehicle depreciation depends on vehicle usage; the more a vehicle is driven, the less it is worth. Using the Kelly Blue Book to compare resale values of sedans, Todd Litman (2010) suggests that every passenger vehicle-mile traveled costs 18 cents in value depreciation. The American Automobile Association (AAA) suggests that the average new sedan loses value at a rate of 24 cents per mile. Depreciation depends largely on how well a vehicle holds its value, which is specific to both the vehicle make and model, so a large range of depreciation values should be expected.

Automobiles also require routine maintenance due to vehicle wear and tear, parts replacement, and associated labor costs. For example, oil changes are common around every 5,000 to 7,000 miles and tire replacements every 20,000 miles or so, depending on driving behavior and maintenance. Administrative costs also come with owning a vehicle. Drivers usually pay a fee for vehicle license and registration, along with vehicle purchase taxes. The AAA notes that many vehicle owners also pay finance charges for loans and leases. It computes a number of ownership costs for the average car, as shown in Table 1.

Fuel prices have impacted the amount that people drive, as well as vehicle ownership levels. The U.S. fuel price is typically much lower than prices in many European countries, while oil-rich states like Saudi Arabia and Venezuela enjoy very low prices (on the order of cents per gallon). Though diesel-powered vehicles enjoy higher fuel economy (thanks to a higher compression ratio), diesel fuel is typically priced higher than gasoline, due to a high

Table 1 Average new sedan ownership and use costs

Fuel costs	14.45 cents/mile
Maintenance costs	4.97 cents/mile
Tires	1.00 cent/mile
Full-coverage insurance	\$1,029/year
License, registration, taxes	\$611/year
Depreciation	\$3,571/year (when driving 15,000 miles/year)
Finance charges	\$848/year

global demand for diesel, the cost of transitioning to lower sulfur diesel fuels, and excise taxes that may be higher than those on gasoline.

Parking costs vary by location and parking structure. Litman estimates that annual on-street parking costs for a single parking space can vary from around \$500 in a suburban location to as much as \$2,500 in a central business district (CBD). This cost includes discounted land purchase, construction, and operation and maintenance costs. Annual garage costs (to the vehicle owner) may range from \$1,900 per space in a suburban location to \$3,800 per space in a CBD. The 2008 average annual (unreserved) parking cost in the United States was around \$1,500. Some of the highest (unreserved) average parking costs in the nation are found in New York City and Boston, Massachusetts, at \$5,772 and \$5,220 per year, respectively.

Automobile owners in urban and suburban areas may have to pay for parking spaces at home, at work, or when they make other trips, for example, for shopping, entertainment, and recreation. Parking costs may be paid on an annual, contractual basis or may be variable and charged at the time of each trip, through a meter, fare box, electric pay space, attendant, or valet. Hourly parking rates vary by region and garage and usually depend on supply versus demand. For instance, the average rate for small urban CBDs may be \$1 per hour of parking, versus \$1.50 per hour in larger CBDs. Free parking spaces are common in suburban and rural areas, in the form of large parking lots. Parking costs and

Table 2 USDOT recommended costs of emissions

Emission Type	Dollars/Ton
VOCs	\$1,700
NO _x	\$4,000
SO ₂	\$16,000
PM _{2.5}	\$168,000
CO ₂	\$5–\$136

parking availability have significant implications on mode choice and vehicle miles traveled.

Indirect and Hidden Costs

In addition to the direct costs of parking, fuel, tolls, and others, there are many indirect costs, such as travel time, which could be spent on other activities (such as earning income at work or enjoying leisure time). Individual value of travel time (VOTT) varies based on how much an individual might otherwise be earning or even a general aversion to driving in general or being stuck in traffic. The U.S. Department of Transportation (USDOT) has recommended hourly values of travel time (in 2000 U.S. dollars) of \$10.60 to \$21.20 per person-hour for local surface modes of travel, \$14.80 to \$21.20 for intercity travel, and \$18.80 for truck driver travel, both local and long distance. VOTT also further varies by trip purpose and circumstance. For instance, if one is late to an important meeting or rushing to catch a flight, VOTTs can run very high, even for the low-income traveler.

Other "hidden" costs to travelers may include external costs imposed on society and the environment. These costs include the impacts that owning and operating an automobile have on others, by reducing available space on roadways and in parking lots, increasing the chance of crashes (by more potential conflict opportunities), and degrading the natural environment. Litman suggests that increased crash rates add about 10 cents per mile, and congestion and environmental costs contribute an additional 4 cents per mile. Roadway land value, fuel externalities, and traffic services contribute another 1 to 2.5 cents per mile. The implicit,

and often subjective, costs of long-term land use changes and equity impacts, due to automobile reliance, are certainly important but are much more difficult to estimate.

Emissions impacts are an external cost that is often estimated, though specific values are subjective and sometimes contentious. Carbon dioxide (CO₂) emissions are especially difficult to quantify, since impacts related to climate change add an additional but highly debated cost. Table 2 shows the USDOT (2011) guidance for estimating pollutant emission costs by type.

Some other external costs that are difficult to quantify are the stress and health impacts of driving in congestion for long periods of time. The physical response to traffic is well documented as a pervasive medical concern, but valuing these irritations is challenging. Time spent in congestion, however, can be evaluated by considering the lost time due to traffic delays (relative to free-flow conditions, for example). The Texas Transportation Institute's Urban Mobility Report estimates that congestion costs Americans \$121 billion a year in lost productivity, including wasted fuel costs and wasted time for trucks moving goods.

Alternatives

An alternative to owning or leasing a vehicle is renting, borrowing, or sharing a ride (carpooling). There are many car sharing organizations around the world that allow members to rent vehicles on a per-minute, hourly, daily, or weekly basis. Car sharing is popular in Europe, especially in Switzerland, and companies like Daimler's Car2Go and ZipCar have been expanding rapidly in North America. Car2Go charges users a one-time membership fee and a per-minute rate of 38 cents (as of 2013 in the United States) to use a two-seater Smart car. This fee includes fuel, maintenance, insurance, and any other fees: users pay only the per-minute rate. ZipCar provides more vehicle choices (such as sedans, trucks, and SUVs) and charges an hourly rate, with initial and monthly membership fees. Such programs provide travel flexibility, facilitating occasional vehicle access, alongside other modes. However, those needing daily, frequent vehicle access typically find car sharing costs uncompetitive.

Driving an automobile involves a significant number of costs, many of which are paid indirectly

or borne by society, rather than by individual drivers. Direct costs vary by vehicle, driving behavior, and location; indirect costs require subjective and variable valuation of safety, pollution, and time/cost impacts. Even as vehicle and infrastructure efficiency and pollution control systems have improved, driving produces externalities that regularly diminish quality of life and the natural environment.

Automobile Safety Inspections and Registration

Automobile accidents by 2012 had claimed the lives of at least 3,572,832 people since the first fatalities in the late 1890s. In order to reduce the number of accident fatalities, highway injuries, and property damage, automobile safety studies were developed. These deal with automobile designs, their construction, equipment, and the development of regulations to minimize highway deaths.

Road traffic safety focuses on roadway design. This area of study seeks methods and measures that protect people and vehicles on the nation's roadways from being injured or killed. It includes studies of all users of the roads: pedestrians, cyclists, motorists, and passengers—including passengers in commercial or other forms of public transportation. The best practices developed to date focus on prevention despite human errors of drivers. In older studies it was assumed that drivers were complying with traffic regulations when often they were speeding or were distracted. The goal of safe road design is to create road environments that will prevent accidents at normal vehicle speeds.

The approach of road traffic safety is to develop a safe system that will prevent death or serious injury in the event of an accident. This is done by keeping the impact energies below the levels that are likely to cause death or serious injury. Prior to the 1970s, automobile frames and bodies were solid. The effect of a head-on crash at 55 miles per hour was likely to be so horrific that drivers and

passengers were not likely to walk away unscathed. Since that time, cars have been built to displace the energies of a crash. The car is usually a total loss, but the driver and passengers are often able to escape without serious injuries.

A major study of automobile safety was issued by the Cornell Aeronautical Labs of Buffalo, New York. It concluded that seat belts and padded dashboards were crucial to preventing injury.

Vehicle accidents are costly to employers when accidents are work related. The costs are due to loss of productivity and to property damage. The toll to humans is often incalculable. Fatal crashes for truck drivers are of higher frequency than in other occupations. Also, many companies own vehicles driven by employees for deliveries, sales, repairs, calls, client visits, and many other reasons. Young drivers are very vulnerable. Nearly half of the fatal injuries experienced by drivers 18 and younger were work related.

A major problem is the number of pedestrians who are killed by automobiles. The impact of being hit by an automobile is much greater for the pedestrian than for automobile occupants. Currently, in the United States pedestrians are injured by automobiles every eight minutes on average. In addition, the odds of the pedestrian being killed are much greater than for the automobile occupants. Nearly 66 percent of people killed in traffic accidents have been pedestrians.

Since the 1970s, improvements in highway design and construction, along with automobile designs, have contributed to declining injury and death rates in first world countries. However, as automobile and other motorized vehicle traffic has increased dramatically in China, India, and in areas of the third world, accidents have increased.

Studies have used the Peltzman effect, which is also known as risk homeostasis or risk compensation. The effect of risk compensation is observed when people adjust their behavior in response to a risk they can tolerate. This means that people behave more cautiously if they feel a higher level of risk and are less guarded if they feel more protected. The theory is a product of road safety research. Studies of a variety of safety interventions did not produce the reductions in risky behaviors nor have the levels of benefits.

Examples of the risk compensation effect were seen in the increases in risky driving behaviors that

occurred with the introduction of seat belts and bicycle helmets. Other increases were observed in drivers who tailgated following the introduction of antilock brakes. In the politics of automobile safety, arguments have been made against the use of safety devices or other safety measures, using risk compensation theory to claim the drivers will just engage in more risky behaviors because they feel safer.

To reduce the effects of risk compensation, which resemble those of moral hazard in economic theory, the concept of shared space is being added to new road designs. The new approach increases the levels of uncertainty for drivers and other road users by removing traditional road markers. The effect is to increase the uncertainty felt by drivers so they slow down. Experiments have demonstrated that shared space can be effective in reducing traffic accidents.

Inspecting vehicles for safety in the United States is regulated by the separate states. Some states have annual inspection requirements. A few have biennial inspection requirements. Other states require safety inspection upon the arrival of a vehicle in the state. Others, such as Georgia and New Jersey, do not have any inspection program. Most states have some kind of automobile emissions inspection if the air quality of the state or a city, such as Atlanta, warrants inspections. Most states have a commercial vehicle inspection program.

In states where a vehicle safety inspection program is enforced, the vehicle is issued an inspection decal to affix to the car windshield or perhaps the rear window. In the case of motorcycles, trailers, and similar vehicles, the sticker is attached permanently to the body of the vehicle. The inspection sticker or decal signifies that the vehicle has passed inspection. It also displays its expiration date. In some states the owner of a vehicle must present proof that the vehicle has passed the safety inspection before the vehicle can receive a license plate ("car tag"), just as proof of insurance is required in some jurisdictions before the license plate can be issued.

In some states the levels of fraud in the inspection programs challenged the efficacy of the inspections. The lack of popular support undermined the effectiveness of the program of safety inspections. Many whose automobiles were new and safe saw the requirement as a waste of time and money. Controversies have arisen at times

over whether safety inspections are cost-effective ways to increase highway safety.

Vehicle registration is usually a government mandate. The goal is to establish a clear title of ownership and then, in most cases, to impose a tax. Titles are one way of combating car thieves, who find it much easier to sell stolen vehicles that cannot be traced easily. The length of time that registration is valid varies among states. Some states require annual reregistration.

A vehicle registration tax may be a nominal fee or an ad valorem tax or some other kind of tax, such as a sales tax on the purchase price of the car. Most jurisdictions require motor vehicles to have a vehicle registration plate that is permanently mounted in a visible place near the engine. In addition, the owner of the vehicle is issued a vehicle registration certificate. In some jurisdictions the car license plate belongs to the owner and not to the automobile. Therefore, when a car is sold, the new owner must obtain a new license plate for the car. In other jurisdictions the car tag belongs to the automobile and is transferred along with the registration at the time of the sale of the car.

In the United States vehicle title registration varies from state to state. In most states the registration is handled by the state's division (or department) of motor vehicles (DMV). In a few states the DMV has another name or registration is conducted by another state agency. In order to legally use a passenger or commercial vehicle on public roads a vehicle must be registered. Vehicles not used on public roads, such as farm equipment or even vehicles used in mines or on private land such as farms, may not be subject to registration.

Automobile Safety Systems

Automobile safety systems have come a long way since Congress passed the first automobile safety standard law in 1959. Today safety is part of the mandatory annual automobile inspection in most states, and manufacturers offer safety features far beyond what is required, either as standard equipment or as an option. Most safety features are aimed at preserving the safety of the driver and passengers; pedestrians remain far more likely to be killed in vehicle crashes, though collision prevention features help somewhat with this. There are, broadly, two types of safety features. Active safety features work to help prevent crashes from occurring. Passive safety features help reduce the injuries and fatalities that result from the crashes that do occur.

Active Safety

Active safety features include such basic features as the car's steering and suspension systems and

brakes, which give the driver control over the vehicle's motion to respond to events; the headlights, signal lights, and reflectors, which help make the car visible to other drivers; and the mirrors, which give the driver a greater awareness of his surroundings. Beyond these basics, there are many more active safety features included in many modern vehicles.

Backup cameras have become increasingly popular, as they provide a dashboard display from a rear-facing camera to assist the driver with backing without needing to swivel back and forth. This may be offered in combination with backup sensors, which sound an alert when the backing vehicle comes into close proximity to an object in its path. Other warning systems alert the driver if the car is too close to the vehicle ahead or has begun to drift out of its lane (which may indicate a driver who is nodding off at the wheel), or let the driver know of changes to the car's condition, such as low fuel, low tire pressure, an overheated engine, or other problems. The driver's ability to respond may also be assisted through infrared night vision systems or adaptive headlights that increase visibility without impairing the vision of oncoming drivers.

Modern cars also possess systems that help prevent loss of control and collisions, such as improved cruise control systems that respond to the proximity of the vehicle ahead of the driver and adjust speed to maintain a safe distance, traction control systems that respond when wheels begin to spin, and electronic stability control systems.

Electronic stability control systems, which some manufacturers call dynamic stability control systems, active handling, vehicle stability assist, or StabiliTrak, were developed at the end of the 20th century and work to ensure steering control by individually braking the wheels as necessary when steering control loss is detected. The system monitors the steering wheel angle to determine the driver's intended direction and compares it to the vehicle's actual direction, derived from observations of the vehicle's rotation, lateral acceleration, and the speed of each wheel. The method by which the system corrects the vehicle's direction is essentially weather independent. While traction control systems help with the loss of control that results from spinning wheels in icy, muddy, or wet conditions, the key scenario in which electronic stability control is needed is when the driver must suddenly

A dashboard display for the adaptive cruise control system in a Volkswagen Golf. Advanced cruise control systems like this can now respond to the proximity of the vehicle ahead and adjust speed to maintain a safe distance.

swerve, such as to avoid a pedestrian or another vehicle. In these situations, stability control assists to keep the driver from losing control of the vehicle. In some vehicles, electronic stability control and traction control are combined. A National Highway Traffic Safety Administration study found that electronic stability control reduces crashes by 35 percent—and by 67 percent for sport utility vehicles (SUVs).

Braking enhancements include antilock brakes, which prevent skidding by preventing the wheels from locking up during braking. Antilock brakes were one of the first major braking enhancements to be adopted, and were originally developed for aircraft. They have been further enhanced with the addition of emergency brake assist technology, which determines the presence of an emergency based on the speed and force with which the driver pushes the brake pedal and in response to an emergency applies the brakes fully. This helps ensure a full braking, even if the driver is startled by the kinetic feedback of fully depressing the pedal. BMW further expanded its antilock braking system with cornering brake control, which applies braking

pressure asymmetrically while cornering, which also helps with stability. Similarly, many manufacturers use electronic brakeforce distribution, which varies the amount of force on each brake based on detected conditions. This helps avoid skids that result from abrupt braking.

Passive Safety

Passive safety features reduce the severity of crashes. For instance, automobiles are designed with a crumple zone that, in the event of a collision, transfers the energy of the crash away from the passengers by controlling the deformation of the vehicle. This is why the body of an automobile may be greatly mangled by an accident in which there are no or only minor injuries. Crumple zones are usually positioned toward the front in order to absorb the impact of head-on collisions, where most impact damage occurs, but rear and even side crumple zones are sometimes found.

The basic function of the crumple zone is to transfer crash energy along the outer elements of the vehicle rather than passing into the cabin (the interior) and causing injuries as passengers are hurt by broken or deformed interior elements. In conjunction with the crumple zone, automobiles are often designed with anti-intrusion bars, which limit the effect of side impacts on the cabin, and with stronger and more resilient materials at the parts of the cabin that experience the greatest forces in collisions. The goal is not only to limit the impact of collisions on passengers but to prevent the cabin from deforming in a way that makes it difficult for passengers to escape the vehicle (or be removed from it by emergency personnel) after a crash.

Seat belts and air bags are the best-known passive safety features. The modern design of the seat belt has gone through many changes, since early studies determined that while seat belts may have prevented one class of injury, they were frequently causing other injuries in collisions. Today's seat belts include a shoulder strap, which prevents the likelihood of the head snapping forward (though shoulder strap usage is not mandated in as many states as seat belt use is).

Air bags may be placed driver-side, passenger-side, or both, and consist of flexible cushions that rapidly inflate in the event of a collision, softening the impact of the passenger against the steering wheel or dashboard. Though designed in the

early 1950s, they were not introduced in the United States until the 1970s; they became popular features in the following decade as American interest in automobile safety increased. Many car models now come equipped with multiple air bags to protect passengers in the case of front, side, or even rear-end collisions.

Windshields and windows are also manufactured to minimize their contribution to injuries in the event of a collision. Windshields are designed to be shatterproof through the application of laminate materials, such that the windshield will crack but will not break into pieces. Side and rear windows are designed to break into small blunt pieces that cause minimal injury.

Automobile Tires, Nitrogen Inflation and

The use of nitrogen instead of air to inflate automobile tires may provide benefits in the areas of fuel efficiency, maintenance, and safety. Though not widely available to the average consumer in the past, nitrogen tire inflation has been used for

many years in performance settings such as Formula One and NASCAR racing vehicles and Tour de France bicycles. Nitrogen gas also has been used to inflate tires for some off-road heavy equipment and for both commercial and military aircraft. The National Aeronautics and Space Administration (NASA) used nitrogen-filled tires for its lunar roving vehicle. The main reason nitrogen is not yet the inflation gas of choice for consumer car and truck tires is that for many years there had not been a cost-effective way to obtain it.

Some manufacturers found a way to tap the potential of nitrogen gas in the consumer market using cost-effective membrane technology systems for extracting pure nitrogen from compressed air. The systems can be used with existing compressed air systems at dealerships and gas stations, keeping costs low and making nitrogen available via the same delivery network as oxygen inflation.

Benefits of Nitrogen

With conventional air-filled tires, tiny oxygen molecules leak out through the permeable rubber tire walls at a rate of approximately 1.5 pounds per square inch (psi). This causes tires to be underinflated in as little as one month if not checked regularly. The process also oxidizes and weakens the tire's steel belt structure and facilitates moisture and contaminants that further shorten the life cycle of the tire.

Nitrogen molecules are larger than oxygen molecules and take as much as six times longer to reach the same level of leakage and underinflation. Nitrogen gas also is very clean and does not hold moisture. Keeping moisture out of tires significantly reduces the likelihood of valve corrosion, tread separation, belt failure, and other causes that can lead to tire blowouts. Nitrogen is noncombustible as well, and tires filled with nitrogen do not heat up and expand, which improves overall tire performance. Moreover, because it is a naturally occurring inert gas—accounting for 79 percent of the air humans breathe—nitrogen is environmentally safe and has a shelf life of more than 20 years if appropriately maintained.

The use of nitrogen in tires also helps protect the environment and generate savings by providing better ability to retread worn tires. Retreading makes an old tire serviceable again by removing and replacing worn and damaged rubber belts, or treads.

In this way retreading extends the useful life of the worn tires and decreases the production need for completely new tires, which saves millions of gallons of oil each year and reduces use of finite rubber resources and loss of natural habitat. Keeping tires longer also lessens the volume of solid waste from trashed tires in need of disposal. Retreading also lowers costs for companies and consumers because retreading is less expensive than purchasing and installing new tires. For many commercial vehicle fleet businesses, tire replacement is the third-largest line item in the operating budget. By increasing the use of retreading, companies can generate significant cost savings for the bottom line.

Proper Tire Inflation

A number of service equipment manufacturers developed on-site nitrogen generator systems that utilize a selective permeation approach to separate oxygen and moisture from a site's existing compressed air lines in order to capture nitrogen. The key feature of such systems is a membrane that separates the gases, allowing oxygen and water vapor to be removed, leaving essentially pure nitrogen that is stored separately until it is needed to inflate tires.

The generators, which are typically set to deliver the recommended 145 psi of pressure required for optimal nitrogen tire inflation, are generally anchored to the shop floor and connected to the existing air system's inlet valve. No other equipment is needed for operation except a hose to inflate the tires. The systems are maintained through regular nitrogen calibration and replacement of filters and gas analyzers.

Tires that contain both air and nitrogen should be emptied and then reinflated with the appropriate volume of nitrogen to ensure safe and effective operation. In cases where a mixture of both oxygen and nitrogen inflation are utilized—when nitrogen inflation is not available, for example—it is best to match the combined mixture in all tires. In other words, if a nitrogen-inflated steering tire has been repaired and refilled with air, it is recommended that nitrogen be let out of the other steering tire and refilled with a similar amount of air until both tires can be purged and reinflated with full nitrogen pressure.

It is still important for drivers to check tire pressure regularly, regardless of which inflation method is used. The National Highway Traffic Safety

Administration (NHTSA) estimates that more than 27 percent of vehicles on the road drive on significantly underinflated tires. Tires that are underinflated are more likely to prematurely fail, leading to potential blowouts, incidents, and accidents. In underinflated oxygen-filled tires, the rubber flexes more than it is supposed to when the tire rolls. The flexing leads to distortion that generates heat, which in turn accelerates tire wear and additional pressure loss. The cycle is worse in hot weather. For every temperature change of 10 degrees Fahrenheit, there is a corresponding loss of 1 psi in tire pressure. Nitrogen-filled tires are less prone to chemical reaction and temperature fluctuations. As a result, pressure remains more constant over time. This helps preserve proper tire inflation longer and reduce chemically induced aging of tires. Reduced corrosion helps tires maintain their original properties longer and provides increased tire integrity.

Properly inflated tires not only reduce the chances of a tire blowout but also help ensure that appropriate tire contact is maintained with the road. Proper tire-to-road contact improves the vehicle's handling, enabling drivers to react more quickly and smoothly when dealing with potentially dangerous road conditions and situations. According to the NHTSA, correct tire inflation could help save as many as 50 to 80 lives per year and prevent anywhere from 6,600 to 10,600 injuries annually.

Properly inflated tires provide less rolling resistance as well, which helps increase overall fuel economy. The more stable tire pressure provided by nitrogen inflation also optimizes tire function, which can improve fuel mileage by as much as 6 percent. Coupled with less wear and tear on tires in general, nitrogen inflation offers potentially significant cost savings due to better fuel mileage and reduced maintenance and replacement requirements.

Recognizing the safety, efficiency, sustainability, and cost benefits of nitrogen gas inflation, powerhouse retailer Walmart included in its 2011 sustainability program a requirement for nitrogen-filled tires across its entire North American fleet.

Automobile Travel Patterns

Every eight years, the Federal Highway Administration (FHA), in the U.S. Department of Transportation, administers a comprehensive national survey of travel patterns and behavior called the National Household Travel Survey (NHTS). The most recent survey is the 2009 NHTS (conducted from April 2008 to April 2009), which was preceded by the 2001 NHTS and five predecessor surveys, the Nationwide Personal Transportation Survey (NPTS), from 1969 to 1995. Every area of the country is surveyed in an attempt to quantify travel behavior and discover changes in travel behavior over time, while analyzing the relationship between travel behavior and demographics. Data collected concern mode of transportation, distance, duration, and purpose, as well as demographic, economic, and geographic information about travelers.

Information is made available to the public as well as to urban planners, state departments of transportation, and transit agencies, in an effort to better meet travel needs and plan transportation policies. The 2009 NHTS was also the first to collect information on hybrid and alternate fuel vehicle usage and ownership, the delivery of purchases made online (and the effect on driving for errands and shopping). It also asked more granular

questions about employment-related travel, including questions about work-related travel for self-employed individuals.

Vehicles included in the NHTS include all privately owned passenger vehicles, including cars, pickups, vans, SUVs, and motorcycles. The survey did not include rental cars or taxis, cars that are part of a corporate or government fleet, or farm vehicles like tractors. The earliest NPTS did not count pickup trucks, which were primarily used as work vehicles at the time. The 2009 NHTS found 212 million licensed drivers (roughly equally divided by gender, which had been true since 1990), a steady and expected increase over previous surveys, driving 210 million household vehicles. As had been seen in the previous four decades, the growth in number of both workers and drivers outpaced that of households or persons, though the growth in the number of those driving to work slowed down at a point coinciding with the beginnings of the global financial crisis. Growth in the number of vehicles outpaced all other indicators, though the number of vehicles per licensed driver fell slightly to 0.99 (from a peak of 1.06 in 2001). About 233 billion trips were made in the survey period, for 3,732,791,000,000 person miles of travel.

Most trips surveyed by the NHTS were conducted by privately owned automobile. In 2009, the average household experienced 3,466 person-trips, of which 2,892 (83.4 percent) were by private automobile, 362 (10.2 percent) were conducted by walking, 66 (1.9 percent) by public transit, and the remainder conducted by various other means (e.g., a bicycle). In general, wealthier families conducted more trips: 4,815 among those with a household income greater than \$80,000, for instance, compared to 2,100 among those with a household income below \$10,000. Vehicle trips were very fairly evenly distributed between trips to work (22.1 percent), for shopping (22.6 percent), for family purposes, (24.2 percent) and for social and recreational reasons (21.1 percent).

The NHTS found an average of 3.02 vehicle trips per driver per day, for 28.97 vehicle miles of travel daily. This was a slight decrease in mileage from the previous two surveys (from 32.7 in 2001 and 32.14 in 1995) and a decrease in number of trips from the previous three surveys (from 3.35 in 2001, 3.57 in 1995, and 3.26 in 1990). The average vehicle trip length was 9.72 miles, a slight decrease from

2001 (9.87 miles) but longer than for all other previous surveys. Despite the decline in the number of miles traveled per household, the proportion of household trip mileage by automobile over other means of travel has stayed largely the same since 1990. Driving accounted for 88.4 percent of daily trip miles made in 2009, 88.2 percent in 2001, 91.2 percent in 1995, and 88.4 percent in 1990.

Interestingly, the decrease in trips and vehicle miles traveled (VMT) was seen in nearly all categories. The average number of trips to and from work fell from 479 a year to 457 (553 in 1995), social and recreational trips from 441 to 436, and “other” trips from 537 to 500. The number of shopping trips grew slightly, from 459 to 468 VMT. Annual work-related vehicle miles fell from 5,724 in 2001 (and 6,492 in 1995) to 5,513 in 2009; of shopping-related VMT from 3,062 in 2001 to 2,979 (despite the slight increase in number of trips); of social and recreational VMT from 5,186 to 4,842; and of “other” VMT from 3,956 to 3,515.

Commutes remained the longest trips, with an average length of 12.2 miles, a steady increase from all previous surveys. For non-work-related trips, the lowest income households were the only income group for which the number remained the same. Travel in general is strongly correlated to income, though increases in non-work-related travel level off at the highest income brackets. Men across income brackets make more work-related trips; women make more family- or shopping-related trips, reflecting the tendency of mothers and wives to take responsibility for a disproportionate share of household and child-related errands. In both cases the difference is about the same, with one gender performing about 25 percent more trips in that category than the other. Nearly half of trips by women were for personal or family errands, including shopping and transporting children to school or other destinations. Trips for school, church, and recreation remained gender equal, within the margin of error.

A key finding of the 2009 NHTS was the number of automobile trips covering distances that could have been traversed on foot or by bicycle. Sixty percent of all trips of less than 1 mile were traversed by automobile, for instance. Although the distance would be easily traversed without using a car, other conditions may have discouraged this. Even apart from traveler preference and behavior, bicycle

and pedestrian traffic is frequently discouraged by incomplete streets.

When people live in neighborhoods that lack adequate sidewalk coverage, bike lanes or paths, and safe places to cross the street, they are much less likely to use nonautomobile forms of travel. This reluctance is exacerbated in snowy regions, not only because of the discomfort of the weather itself, but because plowing of streets may create snowbanks that interfere with bike lanes, sidewalks, or crosswalks. For example, failing to shovel a path from the street portion of the crosswalk to the sidewalk presents a serious impediment to pedestrian travel.

As a general rule of thumb there is a correlation between high walkability and decreased automobile use. This has been confirmed again and again by municipal governments seeking to increase bicycle use or pedestrian travel; in communities that succeed, use of automobiles has decreased for short trips, and in some cases automobile ownership per capita has decreased overall.

In studies of time spent in a vehicle, whether as passenger or driver, only those 65 and older and 18 or younger spent less than an average of an hour a day in a car. In contrast, people between 35 and 54 years of age, the group with the largest number of employed parents of minor children, spent the most time in their cars—about 73 minutes a day, down from more than 80 minutes in 2001. Persons 55–64 years old spent nearly as long, about 69 minutes, and those aged 19–24 spent about 62 minutes a day in a car.

Interestingly, average time spent driving did not vary widely by size of city of residence. The average driving time of all drivers in the 2009 survey was 56.09 minutes, for instance. Grouped according to city size, the low was 54.79 minutes (250,000–499,999 people) and the highest was 56.85 minutes (3 million or more). This may reflect traffic congestion more than vehicle use or length of trips: commuting speed did vary somewhat by size of location, with the largest cities reporting the slowest commute speeds, at less than 25 miles per hour, while smaller cities and towns reported speeds about 27 miles per hour. All locations reported slower speeds than in the past and had experienced peak commuting speeds (around 30 miles per hour or just over) in either 1990 or 1995. Largely because of commuting, drivers took more trips per day on weekdays than on weekend days.

Overall, average vehicle occupancy was 1.67 persons per vehicle, marginally higher than in previous surveys. Occupancy rose slightly in 2009 for social and recreational trips, to 2.2 people from 2.03 in 2001. It remained largely the same, within the margin of error, in other categories.

Although the number of all automobiles in the United States rose from 107 million to 113 million between 2001 and 2009, the percentage of households with no vehicle or with just one vehicle also rose during those two years, from 8.1 to 8.7 percent and 31.4 to 32.3 percent, respectively. In 2009 36.3 percent of households had two vehicles, while 22.7 percent had three or more, both slight declines from 2001. There is generally a higher correlation between areas of high population density (where public transportation is more likely to be available and comprehensive) and households with no vehicles. Since 1995, about two-thirds of households in the least densely populated areas have had at least two vehicles.

Though the number of workers increased from 2001 to 2009, the annual commute vehicle trips per worker declined, and the total number of commute vehicle trips remained substantially the same: 51,699,000,000 in 2009 versus 51,395,000,000 in 2001. Commute drives per worker declined from 354 per year to 342 per year, and commuting vehicle miles as a percentage of total vehicle miles remained about the same at 27 percent. Total commute VMT in 2009 was 623,479,000,000, up slightly from 614,548,000,000 in 2001 (which was a decline from 1995's peak of 642,610,000,000).

Driving remained overwhelmingly the most common form of commuting—89.4 percent, down slightly from 90.8 percent in 2001—as it has been for as long as the FHA has been conducting transportation surveys (the low of 87 percent was experienced in 1977, in the wake of two significant gasoline crises). Most of those who drove, drove alone.

Automobile Trips

Everyone needs to travel to satisfy economic and social roles. The number of journeys we make to work, to shop, for education, for leisure, etc., has remained remarkably constant over the last 50 years at about 20 per week. As the real cost of travel has reduced, we have traded longer journeys for less dense housing developments. This change was only possible due to the near universal ownership of automobiles in developed countries and massive public expenditure on new roads. If the journey, for example, to work, is the utility of travel, the time and cost taken is the disutility. We undertake an elaborate calculus in trading off this disutility, including being stuck in traffic jams, against the benefits of nicer housing.

Social Aspirations

After a house, a car is the second-largest life expenditure people make, and a signal of social status that is parked outside one's house, advertising one's perception of social standing. Indeed, auto makers spend a lot of money finding out about people's aspirations and playing to these in advertising. Fifty years ago a car advertisement would show a happy family in a new car driving along the highway. Today the highway is so congested that such ads are avoided. Cars are now advertised in fantasy situations, in the mountains, with clean air and beauty.

Interstate 80 near Emeryville, California, in May 2005. A freeway can usually accommodate about 800 cars per hour per lane, or the equivalent of 960 people per hour per lane.

Economic Factors

In real terms the cost of owning and driving a car has declined over the last 50 years, allowing most families to own a car. Indeed, car ownership is still rising, as multicar households become the norm. This growth of car ownership has been enabled by the cheapness of fuel, which does not reflect the replacement cost of petroleum extraction. Not only is car manufacture, maintenance, and servicing a major employer but auto taxes are an important source of government tax revenue. Governments therefore have had strong incentives to encourage more car ownership and use. Now, however, environmental factors are beginning to cause public health and energy security worries, as most cars are 100 percent dependent on oil.

Distribution of Activities

Where we drive depends on where we live and the distribution of the activities we need to access. These are geographically distributed, influenced by market forces and public economic and planning policies. Walter Christaller's "central place theory"

predicts that high-economic-level activities gravitate to the most accessible nodes of a transport network, in order to capitalize on the largest possible market. Before freeways, these central nodes were major intersections and large stations in the central business district (CBD). Today freeway intersections are the prime location of shopping malls, and distribution depots, where internal economies of scale are possible. Such nodes of course are easily served by cars and trucks, but very difficult for transit, unless a new line is built. This suburban decentralization of high-level activities has weakened the CBD, where road access and parking is more limited.

Transport Purpose

The most important trip purpose is the journey to work, since this provides the economic basis for family life. The automobile has widened the job choice area possible within a one-hour drive time, which is about the average people are willing to commute. Conversely, the availability of an automobile to drive to work decreases the importance of house location, so that families can relocate to exploit better schools or lower housing prices, trading off commute costs against mortgage payments. The second most frequent trip purpose is for education, school or college. For small children in one-car households this means living within walking distance of school or a school bus service. The growth of multicar households means that many children are driven to school and so do not have enough exercise.

Individual and Shared Trips

The average automobile has about 1.2 people for work commute trips and 1.4 for other trips. As the driver is one of these people, it means that most automobile use is single-person travel. For the morning and evening peak such single-person car travel congests roads. A freeway in free-flow conditions can accommodate about 800 cars per hour per lane. In the peak period this is equivalent to 960 people per hour per lane, or about 20 buses.

No wonder many highway authorities have installed bus and other HOV (high occupancy vehicle) lanes to increase the peak period passenger capacity of roads. With few exceptions, such HOV lanes have the effect of worsening congestion on the remaining road lanes, as few

commuters will switch to buses and not enough are willing to share a car to reduce flows on non-HOV lanes. More constructively, encouraging car sharing at workplaces can increase average occupancy to over 1.5 people, or a 25 percent reduction in car use. For companies, this can be a useful economic benefit in releasing parking space at the workplace, which can be used for cost-effective expansion. Such car sharing programs can work best with company incentives.

Family outings for vacations by car are a small minority of trips made but, of course, improve car occupancy. Other long-distance trips by car are also a small proportion of trips, with trips over 50 miles (80 kilometers) being typically less than 5 percent of all trips made. Such long trips made for work purposes are usually single occupancy. There are some examples of informal and organized ride sharing, so that the driver can share the car with a passenger, who pays part of the fuel costs of the trip, therefore providing a financial benefit to both parties. The most informal ride sharers include hitchhikers, which forms a very small minority of trips.

Even in carless households, often trips by car outnumber those by transit, as neighbors, friends, and family provide rides. This is particularly so for elderly people who may not be able to drive for health reasons.

Trip Length and Alternative Modes

The economic incentive to maximize the use of a car is great, since the largest costs—purchase, tax, and insurance—are fixed and the marginal costs—fuel and maintenance—are smaller and depend on distance driven. Indeed, most people do not know the real cost of driving and only think in terms of fuel costs, which are typically less than half of total costs. Therefore, unless there is a distress factor, like illness, or someone's car has broken down, people rarely think of alternative modes when a car is available. The one exception to this is the use of park and ride to use rail transit to the CBD or for a longer business trip.

Given that over half of all car trips are under about 10 miles (16 kilometers) long, rarely will alternative modes be competitive terms of travel time and convenience, unless traffic congestion is chronic. The most widely used alternative to the car is the taxi, a form of public transit often overlooked. In many developed countries the taxi is the most

widely used mode of transport by lower income, carless households. In many U.S. cities taxis are the only form of publicly available transportation.

Environmental Impacts

Peak period traffic congestion has severe environmental impacts, of which air pollution has the most health-threatening results. Cardiovascular and respiratory diseases caused by traffic pollution kill on order of magnitude more people than road crashes. This air pollution killing is more insidious than car crashes. Los Angeles is the world leader in automotive petrochemical air pollution, where typically more than half of the year levels of air pollution are above danger levels, and any outdoor exercise including walking is strongly discouraged. All developed cities with high levels of motorization suffer from the same public health air pollution levels. Had the internal combustion engine been invented in 1998, rather than 1898, it is doubtful that it would have been approved for public use. The main mode of transport before the car, the horse, also polluted but not in a health-threatening manner; its waste products being a useful horticultural fertilizer, and unlike a car, horses are fueled from sustainable sources.

Automobiles, Passenger

The passenger automobile, most commonly known as the car, is a wheeled motor-powered vehicle, which is designed to be driven—primarily along roads—and carry passengers. The word *automobile* is of French origin, from the ancient Greek *autos* meaning self and the Latin *mobilis* meaning an entity that can move itself; the term was first used in the context of passenger transport at the turn of the 20th century.

The introduction of the motor car fundamentally changed society when it began to arrive on city streets in 1885. It subsequently became the dominant mode of personal travel around the world. It reshaped cities from relatively bounded areas of economic activity to vast sprawling urban metropolises; it figuratively made countries and continents much smaller and changed where we live, work, and go about our daily lives. Today the availability of cars of all shapes, sizes, and varieties is vast. We have vehicles that are powered by different fuels with different technological characteristics.

The automobile sector is an important contributor to the global economy. It was estimated in 2010 that there were over 1 billion vehicles in the world, and it is expected that by 2015, the global car market will exceed \$5 trillion in value. On the whole, car ownership is increasing, as more emerging economies build roads and cities following the Western model. The car became the cultural symbol of progress in the 20th century—car ownership was synonymous with prosperity.

The status accorded to the personal automobile endures in society today, despite some of the now-known inherent problems with what Daniel Sperling and Deborah Gordon have called our auto "monoculture." Indeed, the changes brought about by the car have been both positive and negative; while the car has played an important role in both creating jobs and growth and enabled people to travel, it has also contributed significantly to air pollution and the associated health impacts as well as greenhouse gas emissions, which are contributing to climate change. Moreover, the roads built to service the growth in cars have transformed landscapes and perpetuated social inequalities the world over.

Although the automobile can be dated back as far as the 1760s—with the creation of steam-powered automobiles—the conventional internal

combustion engine (ICE), like those ubiquitous in our vehicles today, emerged in the early 1880s—running on fuel gas. Gasoline/petroleum-fueled engines emerged and gained prominence around 1885. Vehicles running on electricity were common around the turn of the 20th century, but the increased use and promotion of the ICE led to the demise of the electric engine until it began to emerge again toward the end of the 20th century as air pollution, energy security concerns, and the need to reduce greenhouse gas (GHG) emissions became apparent. Electric vehicles have begun to come on the market as an automobile that potentially could address some of these social and environmental concerns.

Modern History

The modern age of the passenger car is said to have begun in the 1880s, when German inventor Carl Benz created the Benz Patent-Motorwagen. Such was the popularity of Benz's invention that horse-drawn vehicles, which were the most common form of the transport at the time, were gradually phased out, for the wealthy at least. Development of similar technology was beginning to take place across Europe and also in the United States, and it was in 1897 that Rudolf Diesel—another German—created the first “Diesel Engine.” Indeed, there was a vibrant competition between the fuels during the early period of expansion, with steam, gasoline, and electric vehicles all seeking dominance in the emerging market.

All were viable technologies, but in the early 1910s, gasoline won the battle and has been the leading power source for the global vehicle market ever since. Part of the reason for this may well be due to the fact that in 1908, Ford Motor Company introduced the Model T. Ford's pioneering “production line” manufacturing techniques, which significantly sped up production, enabled the cost of owning a vehicle to be dramatically reduced, and enabled the ownership of a passenger automobile to become a possibility for the masses. The process, which included placing a worker at a distinct point with one specific duty on the production line, became known as “Fordism” and was copied by other manufacturers in the car industry, as well as by many other industries.

Only when Japanese manufacturers pioneered “just-in-time” or “lean manufacturing” processes

was the production line called into question. Such processes reduce the need to keep significant stock on hand and allow the manufacturer to supply a minimal level of products to maximize return on investment—enough to sell but with no left over or latent stock.

Although the typically black Model T fell from favor when a larger range of models and color choices from other manufacturers, including General Motors, entered the market, it is nonetheless responsible for initiating the pervasive spread of the car around the globe and changing our senses of and relationships with space and movement for good. In the early 1920s, after the end of World War I, it was estimated that some 2 million cars were bought every year in the United States alone. By the end of the decade, more than half of all American households owned a car; 20 percent owned two cars. However, the Depression curtailed the rise in car ownership, and World War II saw the car companies retooling so as to provide necessary munitions and turning production away from passenger vehicles toward tanks, airplanes, and the like.

Since the end of the war and until fairly recent years, global car ownership has continued unabated. Road infrastructure has been built to keep pace with the constantly increasing motorization, but demand continues to outgrow the supply of road space, with congestion a fairly ubiquitous problem in cities around the world. And the recent wealth acquisition in rapidly developing economies like India and China has spurred development of massive new car markets.

Rise to Dominance

Streetcars, bus networks, tramlines—the well-established mass transit systems in particular cities, including Los Angeles—were removed to make way for the increasingly popular automobile in the 1930s. And those cities that were less developed by this time saw road building dominate over the provision of other transportation systems. The U.S. Highway Act in the mid-1950s called for the systematic construction of over 40,000 miles of interstate roads to be built across the country; this sealed the dominance of the automobile as the primary mode of choice, and across the Western world the car has become dominant. With the large-scale increase in the construction of roads

and associated infrastructure for the car, including parking and fueling infrastructure, most cities and neighborhoods have been shaped by the car and function around the road network. In many urban areas, provision to travel by other modes is missing or poor and walking and cycling infrastructure does not exist, enabling the dominance of the automobile.

Yet the passenger car has become more than just a mode of transportation. Car ownership is accorded great status as a provider of freedom and has been served and promoted by iconic images of the open road. This symbolism associated with car ownership first seen in the late 1940s and early 1950s has endured over the past 60 years. Similarly, the racing of automobiles has been a commonplace activity since the early advent of the car, with the first organized race taking place in France in 1887. But over the past 100 years, several types of international car racing have evolved and gained popularity, typifying and emphasizing the freedom and enjoyment that can be derived from driving, and promoting luxury and sports car markets around the world. Performance is often a key criterion in the selection of a car to purchase, with top speed and road handling of the car important to buyers, alongside considerations of fuel economy and price.

Congestion, Emissions, and Capacity

As early as the 1960s, at a time when much of the road network was still under construction, it was becoming increasingly apparent that the automobile was having health impacts, causing particular environmental harms and social impacts through its dominance. As the road infrastructure being built became congested at peak periods of the day, the impacts of the traffic building up began to emerge. Smog caused by a photochemical reaction occurring between the pollutants produced by the exhaust fumes of cars running on gasoline and sunlight is responsible for respiratory illness and reduced lung capacity in many global cities. Such health considerations were not understood at the time when urban areas were being filled by automobiles as they became more affordable throughout the 20th century.

As more roads were built to service the increasing population of car owners, significant social inequalities have developed through not only access

to vehicles but also the segregation of communities through road building. Cars are also a significant contributor of greenhouse gases, the primary cause of human-induced climate change.

Move to Alternatives

Since the impacts to health caused by traffic congestion and the internal combustion engine have been realized, the industry has made significant improvements to both the vehicles and the fuels powering the cars—developments such as the catalytic converter and the introduction of unleaded gasoline have greatly improved conditions over the last few decades. But bearing wider issues into consideration, like energy security, peak oil, and climate change, for the last 30 years efforts have been under way to find viable alternatives to the internal combustion engine and automobiles that run on fossil-based fuels like gasoline and diesel. There are particular trade-offs between particular alternatives; for example, while diesel is considered a more efficient fuel than gasoline, it is a more significant contributor to local air pollution that is detrimental to health. Similarly, advances in biofuel vehicles have raised concerns over the competing needs of growing crops for food and crops for fuel. Advances have been made in powering vehicles with gas—both compressed natural gas (CNG) and liquefied petroleum gas (LPG)—but this sector of the total vehicle fleet remains peripheral.

Over the past 10 years, more attention has been paid to the electrification of the car fleet, taking a lead from California's zero-emission vehicle (ZEV) mandate that was introduced in 1990. The Toyota Prius led the way in the late 1990s, offering the first mainstream hybrid vehicle with an internal combustion engine for longer journeys and a battery for city driving. Several of the larger car manufacturers have brought electric vehicles to market over the past few years, including the Nissan Leaf and the Chevrolet Volt; similarly, new manufacturers have entered the market like Tesla, with its luxury brand Roadster and symbolically named Model S.

While the market continues to be dominated by conventional vehicles, recent legislation such as the European Union cars and carbon dioxides (CO₂) standards and the newest iterations of the Corporate Average Fuel Economy Standards in the United States calling for more and more stringent fuel efficiency, vehicle-based technological improvements

and so-called light-weighting brought about through new materials will likely only get the auto manufacturers part of the way; they will need to continue to look to new fuels—electricity, second-generation biofuels, and even hydrogen—in the long term. These standards do not address the impacts that stem from the fact that people continue to drive more and farther year on year or the social or environmental impacts of the road infrastructure itself. Moreover, the shift toward new fuels suggests that the automobile will remain the dominant choice of transportation for decades to come.

national government owns some or all of the major commercial airlines, but in the United States all the major airlines are privately owned and operated. Such status is subject to change: British Airways, for example, was a government entity when formed in 1974 from the merger of two state-owned major operators, British Overseas Airways Corporation (BOAC) and British European Airways, along with two regional airlines. However, British Airways was sold to private industry in 1987.

Scope of the Industry

Commercial aviation in the United States is estimated to generate some \$1.3 trillion in economic activity, or about 5 percent of the total U.S. gross domestic product (GDP). According to the Federal Aviation Administration (FAA), the industry employs or supports the employment of more than 10 million workers. As a factor in global trade, the industry exports about \$75 billion annually in aircraft engines, equipment, and parts—the leading single sector of net exports by U.S. industries since the late 1990s.

The United States has in recent years contributed from one-fifth to one-fourth of total global commercial aviation economic activity. Some of this is indirect. For instance, air passengers within and from the United States spend about \$250 billion on goods and services that they might not otherwise spend if they did not travel by air, the FAA reported. In addition, commercial aviation is a driver of domestic and international manufacturing and retail trades by transporting more than \$550 billion in freight annually.

For several decades at least, commercial aviation has not only driven economic expansion but it also has been a leading force in shaping the very nature, structure, and dynamic systems of the urban, regional, and many rural areas of the United States and other countries. Other modes of transportation have also influenced the overarching trends, but air travel and air transport have exerted a particularly profound influence on the ways and means of interurban, regional, and international commerce in its many ramifications: social, political, architectural, and with regard to policy in the domains of energy, environment, employment, and national security.

Air transport and air travel—the main constituents of commercial or business aviation—exert a

Aviation, Commercial/Business

Commercial aviation composes the largest sector of nonmilitary aviation by economic production value; it includes airline passenger travel, air cargo traffic, charter flights, and additional business-oriented aspects of general aviation. In many countries, the

A Delta Airlines Boeing 747-400, along with ground operations vehicles and several other aircraft, on the runway at Atlanta Hartsfield-Jackson Airport, which is the world's largest with a 2.2-million-seat capacity. The five largest airlines in the world by capacity are based in the United States and include Delta, United, Southwest, American, and US Airways, with a combined 15.5 million seats.

multiplying effect on other sectors of the economy, including but not limited to manufacturing and high-tech research, wholesale and retail trade, construction, hospitality, leisure and entertainment, and various institutional sectors such as education and health care.

Capacity of Carriers and Airports

The top five world airlines by capacity (that is, seats offered) are all based in the United States: Delta, United, Southwest, American, and US Airways. Together these five command some 15.5 million commercial passenger airline seats—equivalent to the next 11 major carriers combined. These next-in-line carriers include China Southern and China Eastern, Lufthansa, Air France, All Nippon, and representatives of other regions.

Only one of the top five airports by capacity offered is in the United States; however, it is the world's most capacious—Atlanta Hartsfield-Jackson. This global hub with 2.2 million total seat capacity is just ahead of Beijing Capital International Airport. Other contenders in the top five are Tokyo Haneda, London Heathrow, and Dubai International.

In the United States, the FAA listed 503 commercial service (CS) airports in its most recent National Plan of Integrated Airport Systems (NPIAS) report. These include both the 382 primary airports, defined as handling more than 10,000 enplaned passengers per year, and the 121 nonprimary CS airports, with annual enplanements ranging from 2,500 to 10,000. The primaries are staggered in size range, classified by the

percentage of total annual U.S. enplanements; these are termed nonhubs, small hubs, medium hubs, and large or major hubs.

Outlook

Industry leader Boeing Corporation in mid-2013 projected a 5 percent annual growth rate for both passenger traffic and cargo traffic worldwide over the next 20 years, and estimated that more than 35,000 new aircraft will be in demand, at a value of approximately \$4.8 trillion. This major manufacturer pointed to wide-body aircraft as the likely answer to many carriers' goals of increasing capacity while cutting fuel consumption. Boeing also projected that Asia will be where the most rapid expansion of the industry continues to take place and will account for more than one-third of all new aircraft deliveries over the coming two decades.

The Boeing projection roughly paralleled a report in 2011 by European rival manufacturer Airbus, which also predicted an approximate 20-year doubling of the worldwide commercial fleet. At the time, Airbus said that demand would equate to some 28,000 new aircraft with a value of about \$3.5 trillion. The Toulouse, France-based company envisioned revenue passenger mileage expanding by nearly 5 percent annually over the next 20 years, another perspective on the doubling of air traffic by 2030.

In sync with the later Boeing analysis, the Airbus projection foresaw Asian-market volume making up about one-third of the total traffic. In particular, the analysts at Airbus projected the U.S. domestic flights to log 11.1 percent growth, followed by India at 9.8 percent air traffic growth, western Europe at 7.5 percent, and China at 7.2 percent.

The Centre for Aviation (CAPA) in its 2013 outlook identified Persian Gulf commercial air carriers as poised for continued strong growth, along with those in China, and to a lesser extent the carriers in the emerging national economies in India, Africa, eastern Europe, and Latin America. The report was not entirely positive, however, as it led with the observation that many major commercial airlines are operating in a risk-reduction mode as opposed to an aggressive or optimistic growth phase.

This analysis stems from several years of a somewhat lagging volume curve in the wake of the global financial distress that began in 2008, with its lingering atmosphere of general economic uncertainty.

Fully 15 percent of premium commercial air passenger traffic vanished in the immediate wake of the 2008 crisis—and there has been scant recovery of this vital source of global aviation revenues in the five years since.

Layered over the background uncertainty, CAPA noted, was the persistent upward pressure on fuel prices and a still-lackluster demand level for commercial air service in the developed economies of Europe and North America. The report indicated that even for fuel prices to hold at current levels would be a positive benefit, and noted that fuel surcharges added to customer tickets were more of a travel agency fee—neutralizer than any real savings or gain to operating incomes. The report cited the real threat of secondary route reduction and other cost-cutting measures that numerous air carriers would be compelled to take should fuel prices spike or trend strongly upward. Tertiary threats included what the industry considers relatively high tax structures, somewhat high labor costs, and in some regions a marked evidence of too much capital sunk in fleets and infrastructure—in other words, a condition of overcapacity.

The CAPA analysis painted European operations as heavily in debt, U.S. carriers “forging a shaky recovery” but also debt ridden, but Asian operators as better positioned cash-wise and enjoying various incentives. The report concluded that most major carriers have already enacted policies to cut risk by building partnerships and ancillary business, hedging on cash flow, improving their lease positions, and, above all, squeezing capacity—hence the strong inherent demand for new wide-body jets as detected by the manufacturers' reports.

aviation is part of the larger realm of general aviation, which as a whole contributes on the order of \$75 billion annually to the U.S. economy, according to the Federal Aviation Administration (FAA). This figure includes operations of nearly \$39 billion and combined manufacturing and traveler expenditures of approximately \$37 billion each year.

Research by the FAA has shown that average annual earnings of private aviation workers—both those directly employed in private aviation and those working for support enterprises from manufacturing to distribution to ground services—are nearly equivalent to the earnings of workers in similar positions within the commercial aviation industries, both direct and ancillary.

In its 2011–2015 National Plan of Integrated Airport Systems (NPIAS), the FAA indicated that 2,829 public airports in the United States are designated as "reliever airports" or as general aviation airports, that is, they offer noncommercial service only; specifically, 2,560 general aviation airports and 269 reliever airports. To be listed in the NPIAS, general aviation airports must be open to the public, be located within 20 miles of the nearest NPIAS-listed airport, and base at least 10 aircraft. Reliever airports must base at least 100 aircraft or at least 25,000 itinerant operations annually. These nearly 2,900 GA and reliever airports make up more than half of all public airports in the United States.

The aircraft of choice in private aviation tends to be of the piston engine type. Roughly 60 percent of GA flight hours were conducted in piston-driven fixed-wing craft; the remaining 40 percent of flight hours were accomplished in roughly equal parts by turboprop, jet, and rotorcraft.

Aviation, Private

Private aviation is a component of general aviation (GA), which also encompasses such noncommercial segments as search and rescue, law enforcement, medical transport, and emergency evacuation. Agricultural aviation is also considered within GA.

Infrastructure and Fleet

There are an estimated 39,000 private aircraft worldwide; as many as 1 million people in the United States work within or in association with the private aviation industry. The domain of private

Private Pilot Qualifications

In most countries, private aviation pilots must obtain certification by a national licensing body. The pilot must determine the type of aircraft for which he or she wants to earn the certification; these range from gliders to airplanes to helicopters, and other flight devices. Beyond the initial private pilot certificate or license, a pilot may decide to qualify for additional levels of ranking, rating, or endorsements. These add-ons may cover qualification for such skill sets as instrument-only piloting, for example, or may be specific to certain aircraft configurations, such as single- versus multiengine craft, or to high altitude-capable pressurized aircraft.

Supporting requirements in addition to the pilot license itself typically include qualifying for such documents as medical certificates. These are classed by criteria based on age, vision, hearing, and other essential health metrics. Some types of certification are nonpilot types; these can apply to flight engineers, instructors, dispatchers, attendants, and related professions. Some of these have distinct rating or class certifications.

The FAA recorded more than 610,000 active airman certificates (pilot licenses) in the United States at the end of 2012. Of these, approximately 188,000 were private aviation pilots, 116,000 were commercial aviation pilots, and nearly 146,000 were certified as airline transport pilots, the highest rating.

Slightly more than half of all active airmen certificates had instrument flight ratings. Nearly one-fifth of the total active certificates were student pilot licenses. In addition to the pilot certificates, there were more than 701,000 active nonpilot certificates, of which nearly half were certified as mechanics; flight attendants were the next-largest cohort, at 172,000, followed by ground instructors, flight engineers, repairmen, dispatchers, and others.

From DIY to Luxury

The scope of private aviation extends from the garage mechanic, do-it-yourself types who build and fly ultralight aircraft, to the elite pilots and owners of sleek executive jets and jet helicopters. Most participants in private aviation, however, are found somewhere in between. Owners and operators of private aircraft must pay airports for the use of runways, terminal space, and other facilities.

While some private pilots own—or even build—their own craft, many rent or lease them. At the higher end of the price spectrum, where individual aircraft may be valued in excess of \$10 million, to say nothing of operating costs, the phenomenon of fractional ownership is popular. While a practical solution, fractional ownership has also given rise to certain contention over tax issues, based on the question of whether such scenarios represent true private aviation or are actually more of a commercial enterprise.

The budget of the FAA is supported in part by a tax on airline passenger tickets. The fact that such a tax is not applied to private aviation passengers, while sensible when considered broadly, is nevertheless at the root of this controversy. One recent

prominent case was the contention between NetJets—which along with its ancillary firms operates the world's largest private aircraft fleet with more than 650 aircraft—and the Internal Revenue Service (IRS), wherein the IRS asserted that the company is at least in part a commercial carrier. NetJets and the IRS wrangled over the issue in 2011 and 2012. Maneuvers toward an eventual settlement featured apparently successful lobbying, for a legislative compromise solution has involved amended FAA guidelines that would add a general aviation fuel surtax, instead of a federal excise tax, on the managers of fractional-ownership air carriers.

There exists the potential for some built-in friction between private and commercial pilots and operators where their paths overlap, in particular, at general aviation airports. Private pilots, for example, often find it difficult to operate at those general aviation facilities that are congested with commercial flight activity, which involves such hazards as aircraft moving at higher speeds and generating higher wake turbulence as well as use of different air traffic control procedures that are chiefly tailored to commercial operators. Recognizing these difficulties, the FAA has made it a policy to encourage development of more general aviation capacity in and near major urban areas; much of this capacity takes the form of reliever airports.

While the FAA and the industry have been somewhat successful in this initiative, it has also meant a diminishing presence of private pilots at such nominally general aviation facilities as the Dallas–Fort Worth, Seattle, and Hartsfield-Jackson Atlanta airports, where they currently make up less than 1 percent of operations.

of the U.S. Department of Transportation (USDOT) regulates such certification requirements. The United States is considered to have rather lenient rules on ultralight aircraft in comparison with other countries that use similar technology.

Why Ultralight Aircraft?

Flying ultralights is an exhilarating sport when done safely. It is not associated with the prestige of owning an aircraft but typically is viewed as a sport that allows the passenger to experience flying in a different manner. Many people are interested in flying ultralight aircraft because they are less costly, there is a minimal amount of training required, and it is considered exhilarating to feel the wind in your face, fly low and slow, and enjoy flying a simple aircraft recreationally. Unlike traditional airplanes, which are used to transport people and goods, ultralight craft are used primarily for sport, and the regulations that pertain to them are less restrictive. Pilots face fewer rules and operational systems. In terms of cost, however, while they are less expensive in terms of fuel, it is relative to the distance they travel and not necessarily less expensive than conventional civilian airplanes.

Many question the safety surrounding ultralight airplanes. While they are considered safe, this is dependent upon those who build and develop them following proper standards and procedures. Pilots are responsible, in large part, for their own safety by observing what they feel is incorrect or potentially dangerous. Learning the general behavior of the aircraft is important when one is first training to be able to spot signs of an improper aircraft on one's own. Ultralight vehicles, however, are inherently safer than conventional airplanes in that they simply travel at reduced speeds and have lighter vehicle weights. When accidents arise, however, it is observed that they coincide with other causes of aviation accidents, which result from a lack of proper instruction or training in extreme circumstances.

Aviation, Ultralight

Also referred to as microlight, ultralight aviation is the flying of lightweight aircraft that accommodates one traveler. In developed countries, ultralight airplanes account for the majority of civilian-owned aircraft. In Canada in October 2010, the ultralight aircraft fleet comprised up to 19 percent of the total civilian aircraft registered. The United States does not register ultralight aircraft, although there are certification requirements for both aircraft and pilots. The Federal Aviation Administration (FAA)

Definition and Regulation

Section 103 of the Federal Aviation Regulation (FAR) governs the use of ultralight aircraft and the responsibilities that fall upon their pilots. Ultralight aircraft are intended by the FAA to be used only for sport and recreation, operated in daylight hours, not flown over congested areas, have only

a single occupant, carry a maximum five gallons of fuel, yield right-of-way to all other aircraft they encounter, and obtain permission to fly and operate in controlled airspace and restricted areas. Ultralight vehicles may be operated during the twilight periods—30 minutes before official sunrise and 30 minutes after official sunset—or, in Alaska, during the period of civil twilight if the vehicle has an operating anticollision light visible for at least three statute miles and the flight is only in uncontrolled airspace. Ultralights are defined as weighing no more than 254 pounds of powered empty weight and having one seat, a maximum of 155 pounds of unpowered empty weight, five gallons of fuel capacity, 55 knots of maximum full-power speed, and 24 knots of maximum power-off stall speed. Craft that exceed this definition in any manner are not considered ultralight.

The FAA chose not to regulate and impose many federal regulations regarding pilot certification of ultralight vehicles but rather left this responsibility to the ultralight community, which came up with a number of requirements. Their suggestions have since gained FAA approval. The industry's self-regulation policy, however, relies upon continued compliance from the ultralight aircraft community. It is the responsibility of the aircraft owner to ensure the vehicle is safe to fly. Manuals are available for owners to determine how the FAA determines safety requirements for their particular aircraft. Registration is available through the United States Ultralight Association (USUA).

Pilot Requirements

Similarly, the FAA does not certify ultralight-specific pilot knowledge and proficiency but expects such pilots to complete training under federally recognized programs. The USUA emphasizes that just because flying a lightweight airplane may look simple does not mean that extensive training should not be taken. Ultralight airplanes are identified as planes that only hold one passenger, although the training, whether sport or private pilot licensure, prepares pilots for two-passenger craft. These planes, however, must be registered with the FAA and possess a federal airworthiness certificate.

Instruction for ultralight airplanes usually requires 10 to 15 hours before one is allowed to fly alone. Federally recognized flight schools and instructors are available through the USUA.

Additional regulations include minimum age limits, medical certification, and completion of FAA-guided written, oral, and flight tests.

There are two different licenses an ultralight pilot can obtain: a sport pilot license or a recreational and private pilot license. Sport pilot licenses allow the licenseholder to operate a plane that meets the requirements of a light sport aircraft with a minimum of 20 hours of training; the minimum age to obtain this license is 17. The recreational and private pilot license allows a pilot to carry one passenger in an aircraft. The minimum flight instruction and solo hours are set at 30 hours and, like the sport license, the minimum age is 17. This license can be used only for flying during daylight hours. Fewer than 300 individuals nationwide currently hold this license, and many continue training to receive their private pilot license.

Aviation Safety, Dangerous Goods Transport and

Dangerous goods are defined as those materials that may cause danger to an aircraft and/or its

passengers if they are carried aboard, either in the cabin or as cargo. Many everyday items actually can be quite dangerous when transported by air. Variations in temperature and pressure during a flight may cause items to leak or break, which may generate toxic fumes or ignite a fire. As a result, many substances, including some seemingly innocuous items, must either be prohibited from air transport altogether or carried aboard only after meeting specified restrictions on their packaging, quantity, stowage location and proximity to other items, and category of flight (passenger plane or freight).

Though some prohibited dangerous goods may be carried onboard an aircraft by passengers who are not aware of the regulations, or who deliberately flout them, there are many permitted items carried aboard aircraft that also have potential for causing or exacerbating a hazardous incident.

Dangerous goods are routinely carried on board both passenger and cargo aircraft. They pose minimal hazard while in transport as long as they are correctly identified, packaged, and handled. If not, those same items could be potentially harmful to all onboard. To ensure safety, it is critical that airline operators take actions to facilitate awareness and education about potential dangers by displaying notices for passengers at airport ticket desks and check-in areas, ensuring that regulations regarding the transportation of dangerous goods are strictly adhered to by all ground personnel and flight crews, and providing detailed procedures for dangerous goods handling and emergencies to all employees who might come into contact with dangerous goods being transported by air.

Dangerous Goods Classifications

The International Civil Aviation Organization (ICAO) was created in 1944 as a specialized agency of the United Nations. Serving nearly 200 member states, the agency promotes the safe and systematic development of international civil aviation around the globe. It is responsible for setting standards and regulations necessary to ensure aviation safety, security, efficiency, reliability, and environmental protection.

The ICAO developed the “Technical Instructions for the Safe Transport of Dangerous Goods by Air” to provide air operators with regulations for transporting dangerous goods. The ICAO defines

dangerous goods as items or substances that pose potential risk to health, safety, property, or the environment. Goods classified as dangerous fall under one of nine hazard classes. Each class, and subsections within each class, is assigned a specific label and iconography that is displayed via a diamond-shaped placard system to ensure speedy and accurate identification. For example, a white diamond with a skull and crossbones identifies poisonous items, a red diamond with a flame symbol is applied to items with potentially flammable liquids and gases, a red-and-white striped diamond with a flame indicates potentially flammable solids, and a blue diamond with a flame indicates goods that are potentially flammable when wet.

The International Air Transport Association’s *Dangerous Goods Regulations* document was developed in alignment with the ICAO technical instructions and provides air operators with a guide for identifying, packaging, and labeling dangerous shipments in accordance with national and international air regulations.

There are nine specific hazard classes for dangerous goods. Class 1 includes explosive substances, explosive articles, and pyrotechnic devices such as fireworks and munitions. Class 2 covers flammable gases, which are gases such as acetylene and hydrogen that ignite on contact with an ignition source; nonflammable gases that do not ignite and are not poisonous; and poisonous gases such as hydrogen cyanide that are likely to cause serious injury or death when inhaled.

The third hazard class for dangerous goods is flammable liquids, which include common items transported via air, such as perfume, alcohol, and fuel. Class 4 encompasses flammable solids like matches, spontaneous combustibles such as coal and linseed oil, and solids such as sodium and potassium that emit a flammable gas when wet or react with water when wet.

Hazard Class 5 includes oxidizing agents that are not natural, such as ammonium nitrate and chemical oxygen generators. It also includes organic peroxides, such as fertilizer and pool chemicals, that may be explosive or burn rapidly due to their thermal instability, sensitivity to impact and friction, and dangerous reactions when coming into contact with certain other substances. Class 6 hazards include toxic substances like pesticides, which are apt to cause death or serious injury if swallowed,

inhaled, or absorbed through the skin. Infectious substances known or likely to contain pathogens such as bacteria, virus, or medical waste are also included in this category.

Classes 7 and 8 address radioactive materials and corrosives, respectively. Corrosive substances are found in commonly used and transported items such as batteries and can corrode certain metals and dissolve human skin and other organic materials. The final hazard class covers miscellaneous items such as dry ice and magnets. Anything from firearms to scissors that is or could constitute a weapon is also prohibited within airplane cabins.

Airline passengers and crew members are allowed to carry a limited amount of dangerous goods classified as hazardous for their personal use within carry-on luggage. Such items include perfume, nail polish, nail polish remover, small lithium and lithium-ion batteries used in portable electronic devices, alcoholic beverages with an alcohol content below 70 percent, and dry ice used to refrigerate perishables. Fire extinguishers, oxygen for masks, and carbon dioxide gas for inflation devices are other hazardous materials that are permitted within the airline cabin in accordance with regulations due to their roles in onboard emergency response.

ICAO Technical Instructions

The ICAO “Technical Instructions for the Safe Transport of Dangerous Goods by Air” contain detailed instructions to ensure the safe global transport of dangerous goods by air. The requirements are based on the dangerous goods classification system and air transport status. Air transport status refers to goods that are forbidden for air transport under any circumstances, forbidden on aircraft in most circumstances but could be exempted in exceptional circumstances, forbidden on passenger planes but allowed on cargo aircraft, and not forbidden at all on either passenger or cargo aircraft under normal circumstances.

As required by the technical instructions, all dangerous goods must be packaged appropriately and may be subject to quantity restrictions according to the degree of hazard and the type of aircraft—passenger versus cargo—on which the items are being carried. For example, U.S. air passengers are permitted to carry on one 1-quart-sized clear plastic bag per person to accommodate liquids, aerosols, and gels, and those items are restricted

to containers of 3.4 ounces or smaller as a security measure to protect against potentially damaging dangerous goods volumes and interactions. Airport personnel at passenger screening checkpoints are required to ensure compliance with the regulation and conduct additional screening as needed.

There are strict requirements for the marking and labeling of dangerous goods packages and for the documentation that must be prepared whenever hazardous packages are conveyed by air. The ICAO technical instructions require that every package of dangerous goods be inspected externally by the aircraft operator or its contracted agent before transport to ensure compliance with regulations. Packages identified as dangerous goods are subject to loading restrictions, including segregation of packages containing incompatible dangerous goods and special securing of packages in place to prevent movement during flight.

The technical instructions mandate that the aircraft pilot should be informed prior to flight departure about dangerous goods that are on board as cargo and where in the plane they are located. If an onboard emergency arises, the pilot is required, if feasible, to notify air traffic control of the presence of any dangerous goods on the aircraft. The measure is intended to facilitate appropriate emergency response if such services are needed. Air operators are required under the technical instructions to report to the relevant authority all accidents and incidents involving dangerous goods. In turn, each jurisdiction is required to have procedures in place to investigate such occurrences.

The technical instructions include training requirements that apply to all parties involved in dispatching, handling, and transporting passenger baggage or cargo goods classified as dangerous. The requirements include the need for refresher training every two years and the maintenance of specific training records. Shippers must ensure that personnel who prepare loads of dangerous goods receive training or must use the service of another organization whose staff is sufficiently trained. Air operators must ensure that their own personnel and the staff of their handling agents are trained accordingly. All dangerous goods training programs for air operators are subject to approval by the carrier’s contracting state, which is also responsible for inspection and enforcement procedures among its air operators to ensure all

dangerous goods are conveyed in full compliance with the international requirements to ensure consistent safety standards worldwide.

Aviation Safety, Wildlife Strikes and

Since the inception of powered flight on December 17, 1903, wildlife strikes in aviation have resulted in hundreds of human deaths and billions of dollars in damages. Orville Wright reported the first bird strike as early as 1905. Since that time federal agencies, airport authorities, biologists, and pilots have been involved in the investigation, reporting, and solutions to wildlife strike research and mitigation.

The most costly crash to date in terms of lives was Eastern Airlines Flight 375 and occurred on October 4, 1960. The Lockheed L-188 Electra, a four-engine turboprop, struck a flock of European starlings six seconds after takeoff. The relatively small blackbird-sized starlings caused engine damage to three of the four engines and the aircraft subsequently crashed into Boston Harbor, resulting in 61 fatalities.

A wildlife strike can be defined as the impact between an animal of size substantial enough to result in damage to an aircraft. Approximately 97.4 percent of all wildlife strikes involve birds. Other animals involved in strikes include mammals such as foxes, coyotes, alligators, and deer at a rate of approximately 2.4 percent. Reptiles such as turtles, tortoises, and alligators accounted for only approximately 0.2 percent of all strikes. Wildlife strikes can cause damage to engines, landing gear, and structural components of an aircraft. Engines account for 32 percent of all damaged components and in many cases cause either a partial or complete loss of power, resulting in the aircraft not being able to maintain altitude.

The most common type of bird involved in strikes is the gull, accounting for 25 percent of birds identified in bird strikes. The second most common type of bird identified in strikes, approximately 14 percent, are doves and pigeons of various species, followed by raptors at 12 percent, waterfowl at 10 percent, blackbirds/starlings at 10 percent, and all others comprising a mix at 29 percent.

The majority of bird strikes, 92 percent, occur at or below 3,000 feet above ground level (AGL). Within this altitude range, 61 percent occurred 0 to 100 feet AGL, 12 percent occurred between 100 and 500 feet AGL, and 18 percent occurred at 500 to 3,000 feet AGL. Strikes during the approach and landing roll occurred at a rate of 58 percent. Takeoff and initial climb phase accounted for 38 percent of strikes.

Bird strikes tend to occur during the day at a rate of 58 percent. Annually, most reported bird strikes (51 percent) occur between the months of July and October. In contrast, mammal strikes (64 percent) tend to occur at night between the months of August and November. White-tailed deer are responsible for approximately 33.6 percent of all mammal strikes. Even though they represent a small percent of total strikes, deer are a major hazard to an aircraft structure due to the mass that they present in comparison to birds or small mammals. Just as with birds, the landing roll held the highest risk for mammal strikes at a rate of 52 percent.

Identification

Wildlife strikes are reported on a voluntary basis to the Federal Aviation Administration (FAA) via paper

or Internet form. Reports can be filed by pilots or airport personnel. Remains that cannot be identified by airport personnel can be sent to the Smithsonian Institution Feather Laboratory for identification. All reports are reviewed by an FAA staff biologist. The data is kept in the FAA Wildlife Strike Database that is managed by the U.S. Department of Agriculture and can be queried online back to the year 1990. Currently, approximately 45 percent of birds involved in strikes are identified at the species level. Voluntary reports are estimated to account for only 20 percent of bird strikes and \$123 million in annual cost to operators. An extrapolation of that number could be as high as an actual cost of \$614 million annually.

Identification of species involved in a bird strike is crucial to the ongoing effort to prevent bird strikes. Understanding local as well as migratory bird habitats and bird behaviors is a key element in developing and maintaining ongoing mitigation programs. Identifying species involved in a strike provides data for researchers and biologists to investigate in terms of local sight survey, as well as in the analysis of regional flyways.

Identification of species at the Smithsonian Institution Feather Identification Lab can be accomplished through several methods. Often the impact in a strike is violent and remains are limited to blood and feathers. The lab can first use microscopy to examine the downy feathers of the bird. Downy feathers, which are smaller feathers found under the tougher exterior feathers, are unique to different groups of birds and can be used to narrow the species for identification. Further identification includes DNA sequence analysis against the Barcode of Life Data Systems database. Identifying exact species may require the assistance of the Feather Laboratory due to the vast number of species that can exist within a family of bird. The dove and pigeon family of birds *Columbidae*, for example, include 310 known species.

Assessment

After examining all wildlife strikes reported to the FAA, the FAA staff biologist examines the strike history at particular airports that stand out in the data. The staff biologist then forwards a report of data to the appropriate regional personnel in the FAA Office of Safety and Standards. From that point, operators of certified airports are required by regulation to conduct a wildlife hazard assessment.

Under 14 CFR Part 139, airports are typically required to be certified by the FAA if they serve scheduled and unscheduled air carrier aircraft with between nine and 30 seats and are required by the FAA administrator to have a certificate. However, the regulation does allow the FAA to issue certain exemptions to airports that serve few passengers yearly and for which some requirements might create a financial hardship.

The wildlife hazard assessment includes a survey of the airport as well as surrounding areas. Site surveys include marshes, wetlands, waste disposal and trash transfer facilities, underwater discharges, stormwater runoff, and livestock production. Natural marshes and wetlands are habitats for both migratory and nonmigratory birds. Waste disposal and trash transfer facilities are major attractants for scavenging gulls. Stormwater runoff and underwater discharges are attractants for wading raptors that feed on small fish, reptiles, and insects that reside in the shallows of these types of habitats. Larger raptors are less prevalent, but the impact of a blue heron, weighing up to seven pounds, can create heavy structural damage.

Livestock production is an attractant for symbiotic birds such as the cattle egret. The cattle egret follows cattle, horses, tractors, and vehicles and preys on the insects that are stirred up in their wake. A natural feed site therefore also includes the edges of roads and runways. Based on the assessment, a wildlife hazard management plan may be required by the FAA administrator for the certified airport.

Management

A wildlife management plan identifies key personnel involved in implementing and maintaining the plan. It also includes identification of hazardous wildlife attractants on or near the airport, appropriate wildlife population management techniques, a recommendation of necessary equipment and supplies, and training requirements for airport personnel involved. Finally, the plan identifies when and how the wildlife management plan will be reviewed and updated.

Wildlife population management techniques include flight schedule modification, habitat modification, resource protection, repelling/exclusion, and removal. Flight schedule modification might involve restricting flights, for example, during a 20-minute period at sunrise and sunset when large

A Brazilian Air Force jet trailing debris and remains immediately after a bird strike in 2007. As many as 92 percent of bird strikes occur low altitudes of 3,000 feet above ground level or below.

flocks of blackbirds move from their daytime feeding site to their nighttime roost. Habitat modification may include food/prey management, vegetation management, water management, and airport building management/modification. Resource protection includes protection of the habitat through proper use of federally regulated pesticides. Repelling/exclusion can include propane cannons, pyrotechnics, distress call tapes, building modification to reduce nesting, and decoys such as kites.

Swallow-tailed kites, for example, are small birds that prey on small lizards, rodents, and birds. The decoys are light and attached to poles via a thin line. The kite decoys are designed to trail out away from the pole in the wind and appear to be in flight and stalking their prey, thus, deterring small birds from the vicinity. Trained falcons and dogs may also be used to repel birds. Removal may include live traps, pesticides, or firearms for overpopulated or difficult-to-control animals.

Patterns

An understanding of migratory bird patterns is an essential part of understanding the bird strike problem. The U.S. Fish and Wildlife Service Migratory Bird Program is the lead federal agency for managing and conserving migratory birds in the United States, and it manages over 1,000 species. One of the areas of responsibility charged under the Migratory Bird Program is Birds of Management Concern.

These include species that are too few or too many, are involved in societal demands, and may conflict with human interests.

Over 34 percent of all bird strikes involve migratory birds. In 1995, a U.S. Air Force Boeing E-3 Sentry aircraft departing Elmendorf Air Force Base near Anchorage, Alaska, encountered a flock of geese, lost two of its four engines due to ingestion, and crashed shortly after, killing all 24 aboard. In January 2009, US Airways Flight 1549, an Airbus A320, encountered a flock of geese shortly after departing LaGuardia Airport in New York City. Flight 1549 lost one engine and partial power in the other due to ingestion but made a water landing in the Hudson River with only two injuries. The Migratory Bird Program works closely with the U.S. Air Force, U.S. Army, U.S. Department of Agriculture, and the U.S. Environmental Protection Agency to address the issue of aircraft wildlife strikes.

Migratory birds in the United States use four primary routes, or flyways. The Migratory Bird Program sponsors the U.S. Flyways Program. The four flyways in the United States are the Atlantic, Mississippi, Central, and Pacific flyways. Each is administered by a council, which is responsible for the cooperation of each state in the flyway and adjoining nations. The councils are responsible for setting the migratory bird policies and contribute to migratory bird research and management throughout the United States, Mexico, and Canada.

Organizations

The Bird Strike Committee USA is a voluntary organization in the United States and serves as a forum for the exchange of information, wildlife strike data, promotion of new technologies, and professionalism in wildlife management programs at airports throughout the United States. It was formed in 1991 as a liaison with other similar organizations that are members of the International Bird Strike Committee. These organizations hold annual meetings and conferences around the world to share knowledge on the subject.

Benefit–Cost Analysis of Transportation

Benefit–cost analysis (BCA) is the standard procedure to assess projects and policies in the transport sector. The method involves the identification, measurement, and monetary valuation of all effects of the project. This includes the financial costs of implementation and operation of the project and intangible effects such as travel time benefits and gains, environmental impacts, and changes in accident risk. The project is identified as desirable if aggregate benefits exceed aggregate costs. The values of effects occurring in the future are converted to present values using a discount rate. Although the method provides reliable indicators of the worth of the project, it is often criticized due to its focus on issues of economic efficiency and failure to address other social objectives.

Benefit–cost analysis is the most common method to evaluate the worth of a transport project and to compare alternative projects. Transportation agencies and policy makers in most countries use a version of this method to support decisions. The popularity of the method is explained by its relative simplicity and by its strong links with economic theory. The rationale of BCA is that a project generating net benefits is worth undertaking. This relies on the postulate that a project has social

value if the people who are made better off are able to potentially compensate the people who are worse off and still be better off. The method also presupposes that it is possible to assign a monetary value to all (or at least to the large majority of) benefits and costs of the project. As the evaluation of public projects is based on their effects on the whole society, the method is sometimes referred to as social benefit–cost analysis.

The financial costs of the project are an essential component of the analysis and include the initial costs of construction of transport infrastructure or application of transport policies and the operating costs throughout their lifetime. These costs are assessed through the market value of the resources used (including labor and capital). Changes in vehicle costs (such as fuel and maintenance) can also be valued by referring to the market price of the relevant goods. The estimation of the effects of a project in the consumption of these goods should, however, consider several factors, such as changes in travel patterns following the project.

The assignment of a monetary value to other costs and benefits is less straightforward, as most of them are intangible and not traded in the market. The usual procedure in these cases is to obtain a measure of people's preferences, measured as willingness to pay or accept marginal units of the units of the effects of the project. These preferences can be estimated directly by surveys (stated preference

methods) or by assuming that the market prices of goods and services related to the effects indirectly reveal people's preferences over these effects (revealed preference methods).

The assessment of travel time savings or losses is a component of most BCA in the transportation sector. The usual approach is to estimate average travel times before and after the implementation of the project for several types of individuals, trip purposes, and times of day or week. The changes in travel times are then multiplied by unit monetary values of travel time for each type. These unit values are often predetermined, based on recommendations of previous studies or on official standards. In other cases, values can be linked to wages or to other market prices. The evaluation of the aggregate travel-time benefit or cost also requires a forecast of travel demand after the project or policy is implemented, considering induced and suppressed trips and changes in transport mode, routes, or other choices of the individuals in the transport market.

The assessment and evaluation of the effects of the project are also complex in the case of external costs and benefits, that is, impacts on individuals who are not users of the project. This is the case with environmental impacts, which include local and global air pollution, noise, land use, community severance, and effects on wildlife. The quantification of these impacts is not simple, as the effects are uncertain or depend on many contextual variables (for example, meteorological conditions affecting the dispersion of pollutants). The assignment of a monetary value to the effects also depends on factors such as people's perceptions about the extent of the effects, their impact on human health, and the existence of altruistic preferences toward the effects on other individuals or on nonhuman beings. The monetary valuation of environmental effects is often supported by surveys or by hedonic analyses. In the latter case, it is assumed that the housing market is a proxy for costs such as local environmental pollution. Differentials in local rents or house prices can then be treated as indicators of the price of different levels of local air pollution or noise.

The evaluation of safety issues presents similar problems, as there is a high degree of uncertainty in the effects of projects in risk levels. The monetization of property damages is relatively simple, as they can be linked to a market value. However, the assignment of monetary values to human injuries,

fatalities, and lives lost is controversial, due to the sensitivity of the issue. These values are usually inferred from the costs incurred to prevent accidents or from cost of medical treatment or productivity and income losses following accidents.

The BCA method treats the effects of the project occurring in the future by applying a discount rate that converts them to present value. This approach is based on the hypothesis that a monetary value is worth more in the present than in the future. The choice of the discount rate to use in the assessment of a given project is not consensual. The most common method is to use current interest rates for borrowing money. The analysis also needs to specify the period in the future after which benefits and costs become irrelevant or are impossible to estimate.

Criticisms

The use of BCA in transportation has been subject to criticism because of a perceived failure to address noneconomic concerns and ethical issues. Most of the arguments deal with the fact that by measuring benefits and costs through people's willingness to pay, the welfare of individuals with lower ability to pay is given a lower weight. The use of a single measure to assess projects, based on net benefits, is also criticized because it addresses only objectives of economic efficiency and does not consider other social objectives, such as equity in the distribution of costs and benefits among different individuals or income or ethnic groups. Due to these limitations, in recent years BCA has been increasingly used alongside other methods, the most important of which is multicriteria analysis.

Bicycle Commuting

Bicycle commuting is widely regarded as a utilitarian activity and simply a means to get from origin (usually the home) to destination (the workplace) in the least possible time. The commute by bicycle can, however, also provide opportunities for recreation. For example, some cycle commuters may actively seek less direct and more scenic routes so that their journey provides opportunities for pleasure and fitness.

The choice of bicycle for commuting typically depends on distance, terrain, and personal taste. For shorter distances over flatter terrain, utility bicycles with a more upright riding position and which incorporate mudguards, chain-guard, carrier racks, and integrated locks and lights are favored as they allow riders to commute in relative comfort in regular work clothes because of their functionality and more relaxed riding style. These types of bicycles are more common in flatter areas and in countries where functional cycling is more established, such as the Netherlands and Denmark.

For bicycle commutes over longer distances or more varied terrain, hybrid bicycles and mountain bikes with less upright riding positions, a wider range of gearing, and mix of extra components and accessories are commonly used. These types of bicycles are more common in highly motorized economies where commuters typically have to mix and move with the flow of motor traffic.

The bicycle commute can also be integrated with public transport over longer distances. Folding bicycles are gaining popularity because of their portability and because rigid bicycles are typically not permitted aboard public transport vehicles during peak periods. Public bike hire schemes also provide the opportunity for public transport users to use

cycling as an access mode to, or egress mode from, public transport hubs. Fixed-gear and/or single-speed road bikes and other variants have undergone a renaissance in recent years and are used for commuting, particularly among younger riders in some flatter European and North American cities, because of their simplicity and their fashion status.

Personal benefits of bicycle commuting include saving money that would otherwise be spent on fuel or public transport and the opportunity to maintain a healthy lifestyle by incorporating regular exercise into daily travel routines. For companies, it can result in a healthier workforce and less demand for space for car parking. Wider societal and environmental benefits include reduced demands on resources required to operate and maintain a motorized transport system, reduced traffic congestion and associated air pollution, reduced demand for limited space on public transport, improved public health, and improved quality of life and social inclusion in urban areas.

There has been a general decline in the rate of bicycle commuting among countries in western Europe and North America since the advent of mass motorization in the 1950s and 1960s. However, some countries have been successful in reversing this decline and maintaining reasonable levels of cycling within the transport mix. This has been achieved through sustained policy supporting cycling, including containment of urban development to reduce distances between homes and activities (including workplaces), investment in purpose-built cycling infrastructure, restrictions on car use in urban areas, and promotional activities to generate a positive culture toward cycling.

Wide variation in the level of cycle commuting is evident between countries that have traditionally concentrated resources on developing infrastructure for accommodating more motorized travel and those that have attempted to manage motorized travel and that have invested in good-quality cycle infrastructure. For example, in the United States and the United Kingdom, countries that have traditionally neglected cycling, less than 1 percent and 3 percent of all journeys, respectively, are by cycle. This contrasts with 10 percent of all journeys in Germany, 18 percent in Denmark, and 26 percent in the Netherlands. Commuter journeys also represent a much smaller proportion of overall journeys made by bicycle in the United States (15 percent)

compared to recreation (60 percent), whereas in the Netherlands, Denmark, and Germany, and to a less significant extent, the UK, cycling is mainly for practical utilitarian purposes.

Deterrents to cycle commuting include time and inconvenience due to journey distance, difficulty integrating cycling with public transport for longer journeys, lack of real or perceived safe routes between home and the workplace, lack of provision of secure cycle parking facilities at the workplace, complex household travel arrangements, the nature of employment/need to use a vehicle in the course of work, climate and weather, the perceived abnormality of cycling, and the ease and convenience of using other transport options such as the car.

There are general moves by policy makers to encourage bicycle commuting in heavily motorized societies. Municipal highway authorities are being encouraged by government to improve cycle infrastructure and companies are being encouraged to be proactive in supporting their employees' desire to bicycle to work. Measures include provision of secure cycle parking, provision of washing and changing facilities, support for employees purchasing cycles and equipment as salary sacrifice and tax-free benefit, subsidizing regular visits by a "Bicycle Doctor" to carry out maintenance or repairs, and inspiring the workforce to commute by bicycle through promotion and marketing, for example, taking part in annual "Bike to Work" campaigns.

Bicycle Facilities

Bicycle facilities are essential to promote cycling in cities. Dedicated parking for bicycles, changing stations and showers at origins and destinations, as well as wheeling ramps alongside steps, are important complementary cycling infrastructure to cycle tracks, cycle lanes, and traffic calming measures. Bicycle parking should be planned for residential areas and main destinations and transport interchanges. Likewise, it is important to plan facilities for short-stay and long-stay parking, the latter normally requiring some type of weather protection and additional security.

Bicycle Parking

Good bicycle parking is essential to promote cycling. Bicycle parking should be provided at regional destinations, public transport interchanges, local attractors, and residential areas. Two main issues are essential when planning the amount and type of cycle parking: proximity and security. Duration of parking is also important to determine the type of parking supply. By counting the number of bicycles locked to street furniture and to existent cycle parking, it is possible to estimate the amount of unsatisfied demand and increase parking provision. Although there are several types of cycle parking equipment, the Sheffield stand is the most adequate design, as it allows for holding the bicycle and locking both wheels.

Four main approaches to planning bicycle parking can be considered in accordance with the length of stay and the type of user:

- *Mini:* Stands and racks, free and on-street. Designed for short stays and drop-in customers and visitors—up to two hours
- *Midi:* Small-scale, locked and covered facilities. Designed for residents, medium-term parking for visitors and employees—up to eight hours or overnight.

- *Maxi*: Constructed parking for neighborhoods. Designed for residents, should be planned for overnight parking.
- *Mega*: City center parking or at main stations. Designed for city center residents, tourists, employees, etc.

Site Considerations

In order to be effective, bicycle parking should be easy to find and located as close to destinations as possible. Proximity is the key element. It is preferable to have several small clusters of cycle parking spread around the city rather than only a few large parking areas. Nevertheless, normally cyclists are willing to park away from the destination if the parking is designed for a long stay in a high-quality covered and secure parking facility. Parking should also be easy to use and allow locking both wheels of the bicycle without removing the front wheel and to support and lock the bicycle frame. Stands that require the bicycle to be lifted should be avoided.

All high-demand areas such as transport interchanges, tourist places, and other attractors should have cycle parking. This includes workplaces, educational institutions, public transport stations, town centers, shopping centers, entertainment and cultural institutions, stadiums and sports facilities, and recreational destinations such as beaches and parks. Cycle parking use should be monitored in order to increase supply or relocate stands if necessary.

Ideally cycle parking should be free, including cycle lockers and other secure covered parking. If charged, fees should be as affordable as possible. Long-stay parking is as important as short-stay parking, and covered, secure parking should be provided in residential areas, public transport interchanges, and major employment areas.

Types of Parking Facilities

There are five main types of parking facilities:

- *Cycle stands*: Designed for one or two bicycles.
- *Cycle racks*: designed for six or more bicycles.
- *Cycle lockers or boxes*: provide weather protection and added space for storage of helmets, bags, and other accessories; requires a management system and an organization to manage the system.

A serpentine-style bicycle rack in Hillsboro, Oregon, in 2010. This style can accommodate more bicycles than a single Sheffield stand while offering multiple points at which to lock a bicycle.

- *Cycle centers* (guarded cycle parking): collective parking with supervision; offer additional services such as maintenance and repair, bike shop, bike rental, and also may have a small coffee shop.
- *Automatic cycle parking*: bicycle storage facilities in which the cyclist hands in the bicycle at entrance and the system registers and stores the bicycle. The cyclist returns the bicycle with an electronic key.

In residential areas, secure covered parking with restricted access should be provided and could be accommodated within the building, garage, or common area. Additional parking stands for visitors should be provided, being extremely useful in high-density areas and student accommodations. If possible, cycle parking should be located in front of the residences or in the most convenient location in order to reduce travel time by bicycle.

On-street cycle parking should be situated to minimize disturbance to other users of the street, especially pedestrians, and not put cyclists in danger from motor vehicles. There are several cycle stand designs, but the most effective and recommended is

the Sheffield stand. It is an “inverted U” metal tube, set into concrete feet below the surface or bolted to the surface with security locks, allowing two bicycles to stand against it (one on each side) and to lock both wheels of the bicycle without removing the front wheel. Sheffield stands with an additional horizontal crossbar provide extra security and support for small bicycles and are useful as an additional barrier to protect visually impaired people.

Sheffield stands can be installed in a row of three to five stands, creating a cycle rack with capacity to park between eight and 10 bicycles. Small stands that lock only the front wheel are not recommended as they do not allow a secure lock of the bicycle and often create damage to the bicycle itself—these are commonly known as “wheel benders.” Wall loops, wall bars, and locking rings are other easy and affordable solutions that can be provided in places where bicycles are leaned against walls as short-stay parking equipment.

Sheffield stand dimensions are 700–1,000 millimeter (mm) length (800 mm recommended), 750 mm height (+/- 50 mm), tube diameter 50–90 mm (90 mm recommended to increase security of U-locks), corner radii 100–250 mm. Stands should be placed 1,000–1,200 mm apart in order to allow two bicycles to park in each one. A space of 600 mm should be left free between the front of the stand and a wall or curb to accommodate the bicycle. If placed parallel to the wall a minimum space of 900 mm is needed. Stands can be embedded in concrete (250 mm deep) or bolted to the ground.

Cycle lockers provide added weather support and luggage capacity but can be visually intrusive. Therefore, special care regarding the choice of location should be taken when introducing them on streets. There is also the possibility of combining cycle stands or racks with public lockers to store luggage and accessories. Lockers normally require supervision to prevent vandalism but can also be used as advertising space, reducing the operational cost, which is over five times the cost of a Sheffield stand.

Cycle centers can provide space for between 1,000 and 4,000 bicycles and require the payment of a parking charge in exchange for safe and secure cycle parking. These centers normally have other additional services, such as maintenance and repairs, a bike shop selling accessories, bike rental, tourist information, and maybe even a small coffee

shop and/or newsstand to increase viability. In these large parking facilities, designated for long-stay parking, it is common to have two-story parking, which allows doubling the capacity of the parking space. Multistory and automated parking facilities are also efficient ways of enlarging parking capacity within the same space.

Changing Stations and Showers

Providing changing stations and showers at major destinations and especially workplaces can have a significant impact on the choice of the bicycle for daily mobility. By having access to changing stations and showers, employees can freely cycle to work, even making the commute an intensive sporting activity if so wanted, as it is possible to take a shower at the workplace.

If possible, changing stations and showers should be provided with lockers. Lockers allow cyclists to leave shampoo, shower gel, and a towel at the destination, and sometimes even a pair of shoes. Separate facilities should be provided for men and women. The specific amount of space needed will depend of the number of cyclists, but a minimum of two showers and 10 lockers for each station is recommended for a medium-sized company.

It is also possible, although less common, to install public changing stations and showers at major destinations and transport interchanges. In this case, a fee may be charged to use the facility. Alternatively, special agreements with gyms and other sports facilities can be made in order to allow cyclists to use their showers by paying a modest fee or buying a yearly or monthly access card.

Wheeling Ramps

There are several situations in which cyclists use routes previously designed for pedestrians. In these situations there may be footbridges or flights of steps on the way, and cyclists will have to carry their bicycles up or down the steps. In these situations, wheeling ramps should be added to one or even both sides of the steps. These ramps can be either a steel ramp or made of concrete over the steps. Normally a channel 100 mm wide and 50 mm deep is adequate. If made of steel, they should have a non-slip surface to create some traction for the descent.

Wheeling ramps are typically installed on the right side of the steps and can be located either close to a wall or at sufficient distance to allow pedals

and handlebars not to crash into the wall with the bike in a vertical position. In either case, pedestrian movements should not be obstructed by the ramp.

Bicycle Safety

Bicycle safety is a very broad topic. This article focuses on collisions between bicycles and either pedestrians or automobiles. A collision is an impact caused by two or more moving vehicles or bodies coming into contact and exerting force upon each other; whereas, a crash is when a bicycle rider loses control and impacts a stationary object or falls from the bicycle. A collision is a type of a crash but not all crashes are collisions. Moreover, it is important to note that pedestrian and automobile/bike collisions are a small subset of all bicycle crashes, but they are significant from a policy standpoint due to the possible impact on traffic flow and the high potential for serious injury. In all 50 U.S. states and the District of Columbia, bicycles are either (1) defined as vehicles or (2) granted all the general rights and duties of drivers of vehicles when they are traveling on roadways. Many states, counties, and jurisdictions have an additional section in the

legal code regarding additional rights and responsibilities for bicycle riders. In places where bicycle riders may ride on the sidewalk, they typically have the rights and duties of pedestrians. It is best for bicycle riders to learn the relevant legal codes where they ride.

Limitations of Data Collection

Data on bicycle crashes are limited, but existing statistics show that more than half, and possibly the vast majority, of all bicycle crashes are caused by a bicycle rider losing control of the bicycle and falling or crashing into an object. Among capable adult bicycle riders, about 10–15 percent of reported bicycle crashes are collisions with motor vehicles. In these reported collisions with motor vehicles, the bicycle rider was at fault about half the time and the motorist was at fault about half the time.

The primary reason for the lack of good data is that most bicycle crashes and many collisions are never reported, especially minor falls that lead to minimal injuries, which are rather commonplace. Many bicycle–motor vehicle collisions are not well documented or reported. First responders do not consistently log bicycle collisions and hospital and police records are not consistently good. Near misses are not reported or studied carefully, which would be helpful in understanding automobile/bike collisions. The probability of being in a fatal bicycle collision or crash is very low, with a fatality rate of one for every million hours of riding, and the probability of being seriously injured in a bicycle crash or collision is several hundred times more likely than being killed.

Some Trends in the Existing Data

Many or most bicycle crashes are caused by a rider losing control of his/her bicycle and crashing; depending on the population studied, 50–80 percent of incidents are falls or lone crashes rather than collisions. In studies of self-reported accidents of experienced adult bicycle riders, about half of all crashes were lone rider falls or crashes. Among all bicycle riders, including children and the inexperienced, the reported figure is more than 80 percent. These crashes were typically caused by encounters with road hazards, including rail tracks, expansion joints, storm grates, and damaged pavement.

Among experienced adult bicycle riders, about one-third of crashes involved other bikes or

Bicyclists wearing safety helmets ride bikes from a bike-share program on a scenic pathway. Helmets, along with gloves and eye protection, are important passive safety measures. Active safety measures include maintaining control over the bicycle, following the rules of the road and being familiar with traffic law, using good lane positioning, and watching for and avoiding other drivers' mistakes.

nonmotorized vehicles, pedestrians, or animals. Only about 15 percent of the crashes in these studies were collisions between a bicycle and a motor vehicle. This is encouraging for all bicycle riders in that the bicycle rider has the power to reduce the likelihood of crashing by improving bike-handling skills and by maintaining control of his/her bike by slowing down and avoiding risky situations. While it is best to educate and train all bicyclists, the greatest opportunity for safety improvements lies in educating the young and inexperienced.

Some useful generalizations may be made from the statistics that are available, and there is some value in comparing statistics on documented automobile/bike collisions with bicyclist fatalities in regard to assessing the relative severity of hazards under various conditions. It can also be helpful to compare statistics for the general public with those for experienced adult bicycle riders.

Alcohol is a factor in about one-third of automobile/bike collisions on the part of either the motorist or the bike rider. In about one-third of bicyclist fatalities, alcohol is a factor on the part of the bicyclist.

About two-thirds of injury-producing automobile/bike collisions occur in intersections or from cross traffic and about one-third of all fatal collisions involving a bicyclist occur in intersections. The statistics suggest that parallel path collisions are more severe and lead to fatality more often than cross-traffic collisions.

About two-thirds of collisions between bicycles and motor vehicles occur in urban areas, which is generally consistent with population density and ridership patterns. Similarly, the proportion of fatal automobile/bike collisions is about two-thirds in urban areas. Automobile/bike collisions do tend to be more severe in rural areas, although fatality rates are similar between urban and rural areas. This

is attributed to the different road conditions and driver and bicycle rider behaviors in these areas.

There are notable patterns of injury and fatality that vary by age and sex of the bicycle rider. Males of all ages are much more likely to be injured or killed while bicycling than females. The injury and fatality rates for children are much higher than for adults in automobile/bike collisions, especially the 10 to 15 year age group. Compared to adults, children involved in automobile/bike collisions are also about twice as likely to be at fault. Although it is difficult to establish causality, there is a correlation between increases in bicycle traffic and improved road safety for all users.

Impact Speed and Severity of Injury

The speed of an object at the moment of impact is one of the primary variables in how much force is applied upon impact. Studies of automobile/pedestrian collisions consistently reveal that pedestrian injury and death rates increase at higher impact speeds. Not only are fast-moving vehicles a potential threat to those around them, there is also a nonlinear increase in the risk of injury or death at increased speeds.

Effects of Changing Technology

Electric and hybrid cars present special threats to bicycle riders because they are so much quieter than automobiles powered solely by internal combustion engines. Bicycle riders rely heavily on their hearing, and the lack of engine noise of hybrid and electric cars makes it more difficult for bicycle riders to hear an approaching vehicle. Collision rates between hybrid cars and bikes have been observed to be higher than between bikes and internal combustion engines cars.

Methods to Reduce Crashes and Collisions and Mitigate Negative Outcomes

There are design and engineering approaches that use technical methods and there are social approaches and methods for improving safety. There are also plural and hybrid approaches that employ technical and social strategies. Driver and bicycle rider education, better enforcement, and better roadway design have great potential for improving road safety.

Even experienced bike riders can benefit from taking a bicycle safety course. At present there are

many bicycle safety education programs in all parts of the country. There is a nationwide movement called Safe Routes to School that educates and encourages elementary and middle school students to bicycle and walk safely. The League of American Bicyclists runs a nationwide Smart Cycling program that trains instructors and teaches Traffic Skills 101 and other courses. Local bike clubs often offer these courses or variations of Traffic Skills 101. There are also other bike safety educator training programs.

For best safety, bicycle riders should employ both active and passive safety measures. Active safety measures are techniques of active engagement with the vehicular environment on behalf of safety. The core principles of crash prevention while riding a bicycle include: control your bicycle, follow the rules of the road and be familiar with traffic law, use good lane positioning, learn to watch for and avoid other drivers' mistakes. Passive safety measures include using protective equipment such as helmets, gloves, and eye protection. While bicycling, it is important to wear a properly sized and fitted Consumer Product Safety Commission (CPSC) certified helmet. More effective education and law enforcement related to speeding and aggressive and distracted driving can also be especially effective for improving road safety for bicycle riders.

As an individual bicycle rider, safety depends directly on the mechanical integrity of the bicycle. It is best to know how to assess the condition and adjustments of one's own bicycle. If one cannot confidently do this, it is best to seek professional help at a reputable bicycle repair shop. Introductory bicycle safety and mechanics classes are available in many locations and interested parties may seek informal instruction from their local bicycle mechanic. In addition to the safe mechanical functioning of a bicycle, equipment may be legally regulated. Front lights and rear reflectors are typically required at night, and in many locations bikes are required to have brakes that can skid the wheel.

Fundamental bicycle handling skills include starting, stopping, shifting, braking, steering, straight-line riding, scanning, signaling, and performing evasive maneuvers. Three commonly taught evasive maneuvers that nearly any bike rider can readily learn are the "quick stop," the "rock dodge," and the "quick turn." These skills are generally taught as part of the core curriculum in applied bicycle safety

courses for adults. Collisions between bicycles and motor vehicles can be reduced and mitigated by better use of active and passive safety measures, improved roadway design, education, and enforcement for all road users.

the last location of a nearby bike sharing bicycle. Bicycle sharing provides a variety of pickup and drop-off locations, enabling an on-demand, very-low-emission form of mobility. The majority of bike sharing programs cover the cost of bicycle maintenance, storage, and parking (similar to car sharing or short-term auto access). Trips can be point-to-point, round-trip, or both, allowing the bicycles to be used for one-way transport and for multimodal connectivity (first-and-last-mile trips, many-mile trips, or both). Generally, trips of less than 30 minutes are free. Users join the bike sharing organization on an annual, monthly, daily, or per-trip basis. Members can pick up a bike at any dock by using their credit card, membership card, key, and/or a mobile phone. When they finish using the bike, they can return it to any dock (or the same dock in a round-trip service) where there is room and end their session.

By addressing the storage, maintenance, and parking aspects of bicycle ownership, public bike sharing encourages cycling among users who may not otherwise use bicycles. Additionally, the availability of a large number of bicycles in multiple dense, nearby locations frequently creates a "network effect," further encouraging cycling and, more specifically, the use of public bike sharing for regular trips (for example, commuting, errands).

Public Bike Sharing Generations

Over the past five decades, public bike sharing has been categorized into four key phases or generations:

- *First generation:* "White bikes" (free bikes)
- *Second generation:* Coin-deposit systems
- *Third generation:* IT-based systems
- *Fourth generation:* Demand-responsive, multimodal systems (or the next generation of IT-based bike sharing).

First generation: "White bikes." Bicycles are typically painted one color, left unlocked, and placed randomly throughout an area for free use. First-generation systems do not use docking ports. In some of the systems, the bikes are locked; users must get a key from a participating local business and may also be required to leave a credit card deposit, but the actual bike use is free. Many first-generation systems eventually ceased operations due to theft and bicycle vandalism, but some are still operating as

Bicycle Sharing

In a public bicycle sharing system, users access bicycles on an as-needed basis. Information technology (or IT)-based bike sharing can be facilitated through a network of stations (typically unattended) or through dockless bike sharing, where riders use their mobile electronic devices to determine

community-based initiatives. The earliest of these first-generation programs was the Provos' White Bike plan, which began operation in July 1965 in Amsterdam. The first North American program, called the Yellow Bike Project, was launched in 1994 in Portland, Oregon, and operated until 2001. The Green Bike Program in Boulder, Colorado, followed this in 1995. Both of these systems eventually stopped operating because of bicycle theft.

Second generation: Coin-deposit systems. In a coin-deposit system, bicycles have designated docking stations/parking locations where they are locked, borrowed, and returned. A deposit, generally not more than \$4, is required to unlock a bike. Although coin-deposit systems helped reduce theft and vandalism, the problem was not eliminated, in part because of user anonymity. Many second-generation systems are still in operation. The first system, Bicyklen, was deployed in Copenhagen, Denmark, in 1995. The Twin Cities (Minneapolis and St. Paul, Minnesota) also launched a second-generation system in 1995 called the Yellow Bike Program. A number of other coin-deposit bicycle sharing programs were launched throughout the United States (for example, in Austin, Texas; Decatur, Georgia; and Princeton, New Jersey). Community-based first- and second-generation bike sharing systems are still operating in the United States.

Third generation: IT-based systems. IT-based systems use electronic and wireless communications for bicycle pickup, drop-off, and tracking. User accountability has been improved through the use of credit or debit cards. Third-generation bike sharing includes docking stations, kiosks, or user interface technology for check-in and check-out, and advanced technology (for example, magnetic-strip cards, smartcards, smart keys). Although these systems are more expensive than first- or second-generation systems, information technology enables public bike sharing programs to track bicycles and access user information, improves system management, and deters bike theft. IT-based systems are responsible for public bicycle sharing's recent expansion in both locations and scale.

The first IT-based system, called Smart Bike (also known as Vélo à la Carte), launched in Rennes, France, in 1998. Clear Channel Communications, Inc., managed this program. It ceased operation in

Bicycles from the SEVici bike share in Seville, Spain, in 2010. Seville's bike share launched in 2007 and was modeled on a program in Lyon, France. As with other third-generation bike-share programs, it is an IT-based system using smartcards.

2009 when the contract expired, and was replaced by LE Vélo STAR. The first IT-based program to launch in Asia was Smart Bike (later renamed TownBike) in Singapore. It operated from 1999 to 2007. North America's first IT-based system, Tulsa Townies, started operating in 2007 in Tulsa, Oklahoma. This was the first solar-powered, fully automated docking-based system in the world. In Canada, the first IT-based system, BIXI (Bicycle-TaXI), began operating in 2009 in Montreal. Since then, BIXI has expanded to Ottawa and Toronto. In February 2010, Mexico City launched EcoBici.

Fourth generation: Demand-responsive, multimodal systems. Demand-responsive, multimodal systems build upon the technology of third-generation

Table 1 Public bike sharing business models

Business Model	Definition	Example (as of May 2013)
Non-Profit	• Goal of covering operational costs and expanding service • Start-up and operational funding typically are supported by grants, sponsorships, and loans	Denver B-cycle Denver, CO (Operational)
Privately Owned and Operated	• Owned and operated by a private entity • Operator provides all funding for equipment and operations • May have limited contractual agreement with public entities for rights-of-way	DecoBike Miami, FL (Operational)
Publicly Owned and Operated	• Owned and operated by a public agency or local government • Agency subsidizes bikesharing with system revenue	Golden Community Bike Share Golden, BC (Suspended)
Publicly Owned/ Contractor Operated	• Owned by a public agency or local government, responsible for funding and administering the system • Operations are contracted to a private operator	Capital Bikeshare Washington, D.C. (Operational)
Street Furniture Contract	• Operator permitted to operate in a jurisdiction in exchange for advertising rights, generally with street furniture • System funded through advertising revenue	SmartBike D.C. Washington, D.C. (Defunct)
Third-Party Operated	• Operated in partnership with local businesses in exchange for a percentage of the profit • Hybrid operation scheme that can be paired with other business model	Chicago B-cycle Chicago, IL (Defunct)
Vendor Operated	• Operated by the same company that designs and/or manufactures the system equipment (the vendor)	Bike Nation Anaheim Anaheim, CA (Operational)

Source: Shaheen, Susan, Adam Cohen, and Elliot Martin. "Public Bikesharing in North America: Early Operator Understanding and Emerging Trends." *Transportation Research Record*, no.2387 (2013).

systems by implementing enhanced features such as flexible, clean docking stations or "dockless" bicycles; demand-responsive bicycle redistribution innovations to facilitate system rebalancing; value pricing to encourage self-rebalancing; multimodal access; billing integration (for example, sharing smartcards with public transit and car sharing); real-time transit integration and system data dashboards; and Global Positioning System (GPS) tracking.

Business Models

A number of public bicycle sharing business models have evolved with the advent of IT-based systems,

including (1) nonprofit, (2) privately owned and operated, (3) publicly owned and operated, (4) publicly owned/contractor operated, (5) street-furniture contract, (6) third-party operated, and (7) vendor operated. Due to variations in ownership, system administration, and operations, there can be overlap between these models. A description of these models is included in Table 1.

Public Bike Sharing Impacts

Public bike sharing offers a number of environmental, social, and transportation-related benefits. Potential bicycle sharing benefits include

(1) increased mobility, (2) economic benefits (including cost savings from modal shifts and increased tourism), (3) lower implementation and operational costs (in contrast to shuttle services), (4) reduced traffic congestion, (5) reduced emissions and fuel use, (6) increased public transit use, (7) increased health benefits, and (8) greater environmental awareness.

An early member survey of four public bike sharing programs in North America was conducted from November 2011 to January 2012, including Montreal, the Twin Cities (Minneapolis and Saint Paul), Toronto, and Washington, D.C. The survey was administered online for all programs and surveyed both annual and 30-day subscribers. Of the total 10,661 respondents, 6,486 came from the United States and 4,175 came from Canada. The survey probed user perceptions about bike sharing and found that a majority in the surveyed cities felt that bicycle sharing was an enhancement to public transportation and improved transit connectivity. In all cities, bike sharing resulted in a considerable decline in personal driving and taxi use, suggesting that bike sharing is reducing urban transportation emissions, while at the same time freeing capacity of bus and rail networks within large cities.

North American Helmet Use and Crash Rates

Public bicycle sharing experts and users generally perceive helmet laws as an obstacle to bike sharing use because of the inconvenience associated with carrying a helmet, lack of availability for last-minute trips, and the challenges associated with providing sterile shared-use helmets. Some organizations located in jurisdictions with compulsory helmet laws offer complimentary helmets with each bike rental. Other operators sell helmets or offer them through partnerships with local bike stores to provide discounts.

The 2011–12 North American user survey of four public bicycle sharing programs, discussed above, found that the majority of respondents never wear helmets. In Montreal, 62 percent of survey respondents indicated never wearing a helmet while bike sharing, compared to 50 percent in the Twin Cities, 45 percent in Toronto, and 43 percent in Washington, D.C. The survey also found that helmet use ranged between 20 percent and 38 percent while using bike sharing.

In the same North American study of all 19 IT-based public bike sharing programs, researchers

found that operators with more than 1,000 bicycles reported an average of 4.33 crashes per year, those with between 250 and 1,000 bicycles averaged 0.6 reported crashes a year, and those with fewer than 250 bikes reported 0.3 crashes per year. Despite more limited helmet use, the accident or crash rate for public bicycle sharing was quite low in North America, as reported in 2011.

In Vancouver, British Columbia, Canada, three private companies are developing options for providing sterile shared helmets, including a helmet-rental sanitizing machine (for example, SandVault's HelmetStation, a fully integrated helmet-dispensing system that sanitizes the helmets upon return) and disposable helmets.

Bicycles

A timely global trend is the increase in the use of bicycles for commuting purposes. While in many parts of the world bikes are—and have been—used as a necessary component of transportation, it is only recently that their use in industrialized countries is being seen as an attractive alternative to fossil-fuel-burning vehicles. Present roadway infrastructure in many urban areas is not appropriately developed in relation to the needs of cycle commuters. Data show that in the United States more than 40 percent of the trips people take with cars are less than two miles, a distance that could easily be managed on a bicycle by most people with some planning and appropriate bikeways.

Bicycle Commuting

Commuting by bicycle is becoming more desirable as the total benefits are becoming more evident. Not only is cycling beneficial to the environment by reducing air pollution, carbon emissions, and traffic congestion, but it is also a healthy alternative as it increases physical activity, improves cardiovascular health, and reduces obesity rates in communities. As a viable commuting option, cycling also saves individuals the expense for daily travel that might otherwise be spent on fuel. City leaders are finding that planning for more bike travel increases the quality of life in neighborhoods and communities.

Innovations in cycling infrastructure, transportation policies, financial incentives, and zoning laws are being applied in more and more cities, most notably in Europe but also in the United States, Colombia, Australia, and China. In industrialized countries where pro-cycling planning and policies are in place, bicycle commuter rates are highest; the Netherlands, Denmark, and Germany (among

other northern European nations) can claim rates of 20 to 30 percent in urban commutes. For China, once called the “Bicycle Kingdom,” bicycles play a very important cultural role. (During the 1960s and 1970s a bike was considered one the three most important and valuable assets that a family could own.) With increased industrialization and production of cars in China, official planning policies often favor cars, and newer transportation infrastructure often excludes bicycles. Still, many Chinese cities have very high cycling rates by world standards.

Compared to other parts of the industrialized world, bicycle commuting rates in the United States are low—the national average is under 2 percent. However, this transportation trend is gaining momentum. As of 2011, the U.S. cities with the highest (top five) bicycle commuting rates are Davis, California (22.1 percent), Boulder, Colorado (9.9 percent), Eugene, Oregon (8.3 percent), Berkeley, California (8 percent), and Cambridge, Massachusetts (6.8 percent). Large U.S. cities with the (top five) highest rates are Portland, Oregon (6 percent), Seattle, Washington (3.6 percent), San Francisco, California (3.5 percent), Minneapolis, Minnesota (3.5 percent), and Washington, D.C. (3.1 percent). What is promising is that, according to the U.S. Census Bureau’s American Community Survey, from 2000 to 2011, 39 bicycle friendly communities (BFCs) among the 70 largest U.S. cities saw an 80 percent increase in bicycle commuting.

Cycle rickshaws are a type of tricycle, powered by pedaling, and designed to carry passengers on a for-hire basis. They are widely used in cities around the world, most commonly in east Asia.

Infrastructure

Researchers and urban planners are finding that increasing the amount and quality of bicycling infrastructure is key to encouraging bike use for travel to work, to school, or shopping. Some studies have been done to assess the effectiveness of various strategies for increasing the use of bicycles. These include providing on-street bike lanes, off-street bike paths, bicycle boulevards, rails-to-trails, and other bicycling infrastructure, such as speed humps, curb extensions, pedestrian crossways, and cycle tracks, which are on-street bike lanes that are physically separated from motor vehicle lanes. New forms of road markings, such as bike boxes, shared lane markings, and colored bike lanes with graphics and signs, may also encourage bike travel.

Promotional and educational programs, along with municipal marketing programs such as bike-to-work days, BFCs, Safe Routes to School programs, and bicycle training classes have become popular in some urban areas. Additional policies, including parking restrictions, traffic-calmed neighborhoods, parking for bicycles, and accommodations on buses and trains for bikes may all, collectively, encourage cycle commuting.

Bike Sharing

Larger cities may benefit from bike-sharing programs. In 2010, Washington, D.C., together with Arlington, Virginia, launched Capital Bikeshare, a regional program. In September 2011, on the first anniversary of its launch, the city also celebrated its 1-millionth-rider milestone. (It hit 4 million riders in May 2013.) Both Washington, D.C.'s bike share program and New York City's new (as of May 2013) Citi Bike sharing program offer bicycles for citizens to "share" or borrow; the first 30 minutes of each trip are free. Pickup and parking kiosks can be accessed in various locations around the cities, usually within close range of transit rides.

"Third-generation" bike sharing technology implements security solutions, including electronically locking racks or bike locks, chip cards, mobile phones, and Internet, meaning bike users are identified and bikes are more secure. During 2010, four major American cities opened third-generation bike sharing programs: Denver, Colorado, with 500 bikes and 50 stations; Minneapolis, Minnesota, with 700 bikes and 65 stations; Chicago, Illinois, with 100 bikes and 6 stations; and Washington, D.C., with

1,100 bikes and 110 stations. Other major cities and urban areas in the United States are following suit; and some have already experienced great success. A great example of progress in a densely urban area is New York City.

New York City

In 2009, New York City's Department of Transportation (NYDOT) initiated an effort to upgrade cycling infrastructure. More than 50 acres of road space in the city has since been converted from traffic lanes and parking lots to more than 200 miles (320 kilometers) of new bike lanes. NYDOT's strategic plan laid out the accelerated goal of doubling bicycle commuting between 2007 and 2012 and tripling it by 2017. The city reached the goal of doubling bicycle commuting in 2011, a year early. Another goal is to reach 1,800 miles (2,900 kilometers) of city bike lanes in the next 20 years, establishing about 50 miles (80 kilometers) of new lanes per year.

Conclusion

Cities that can expand their bikeways, along with other elements of cycling infrastructure, have a better chance of realizing such a goal. The strategies and policies needed to increase bicycle commuting have been successfully tested over time in many European cities. Communities that implement a more integrated system of strategies tend to be more successful. Along with the added miles of bike lanes and bike paths, there needs to be a comprehensive plan in place, including safety measures, easy bike-to-transit locations, bikes to be rented or shared, cooperation with workplaces and schools (such as showering facilities), and eventually, whole neighborhoods and communities that have more accommodating mixed land-use policies. This means designing communities that incorporate commercial, municipal, and public areas in such a way as to de-emphasize the need for motorized vehicles, and to make walking or cycling a more attractive option.

Bicycles, Electric

While electric cars have captured a lot of attention, electric bicycles are proving to be a dynamic, fast-growing sector of the electric vehicle market. Electric bicycles come in two varieties: powered bicycles (PBs) and power-assisted bicycles (PABs). On PBs, the electric motor operates with a throttle or switch and so provides power assistance without any pedal action. On PABs the power assistance is only provided when the rider is pedaling. Some PABs have a sensor in the crank that matches the power assistance to the needs of the rider (maximum power when needed most, like going uphill, and no additional power when it is not needed anyway, like going downhill). The provision of power assistance reduces or eliminates a number of key barriers to conventional cycling and dramatically increases the accessibility of cycling to a broader range of users.

Market estimates are that global electric bicycle sales were on the order of 24 million units in 2010, with about 90 percent of them sold in China. The

fact that some Chinese cities banned motor scooters and motorcycles powered with internal combustion engines has been a boon for the local electric bicycle industry. However, improvements in technology and design are contributing to growing sales in many countries around the world. Sales elsewhere have been slower, but in Europe sales more than doubled from 2008 (300,000) to 2010 (700,000). Continuous improvements in the technology, particularly battery weight and capacity, along with increasingly stylish designs are likely to contribute to ongoing, if not accelerated, uptake.

Benefits

A number of key barriers to cycling are reduced or eliminated by an electric bike, while many of the benefits of cycling are maintained. Typical barriers created by hilly terrain or lack of fitness are minimized as the rider is required to exert less effort for the same output compared to a pedal bicycle. Less effort also reduces the need to wear cycling-specific clothing or shower at the end of a trip, removing further disincentives. Mode shift options provide significant benefits. People who shift trips from cars to electric bikes report economic savings, reduced gas and parking costs, release from peak travel time traffic congestion, as well as environmental benefits related to reduced private car trips. People who shift from public transport to electric bike, particularly for their commute, report relief from crowded or unreliable services and a sense of freedom and independence.

Significant increases in cycling participation can be achieved with electric bikes as the power assist extends the opportunity to cycle beyond the physically fit. Arguably, the greatest gain is for people for whom riding a conventional bicycle is no longer viable. People who have health conditions that preclude cycling are able to enjoy riding on an electric bike, as are people recovering from injury, surgery, or illness.

Riding sooner and with reduced physical exertion can also help people to benefit from the low-impact exercise and achieve the rehabilitative benefits of cycling. Further, when people actually do pedal their electric bike, there is some level of physical health benefit to be gained. People who are overweight or unfit are able to begin their cycling experience at a gentler pace that may enable them to eventually use a pedal bicycle.

Public Policy

Innovative personal mobility options like electric bicycles have a potentially valuable role to play in advancing the sustainability of our urban transportation systems. However, their integration requires careful weighing of the risks and opportunities they provide in terms of safety, system efficiency, mobility enhancement, energy consumption, and environmental impacts. From a public policy perspective, electric bicycles tend to get little attention because in many jurisdictions they are classified as (conventional) bicycles. Yet, the regulations governing these vehicles vary around the world, and even from state to state within the United States. One crucial feature is the maximum power assistance provided by the electric motor that varies from 250 W in some countries (Australia, Europe, Japan) to 750 (United States). Some regulations prohibit PBs, while others specify a maximum speed (usually about 30 kph) at which power assistance must cut off.

A Caution

The impact of electric bicycles on levels of physical activity requires more investigation. In countries where the existing rate of pedal bicycle use is high, there are some concerns that widespread use of electric bikes may negatively impact people's health. For example, in the Netherlands, where almost 40 percent of trips up to 4.5 kilometers are currently made by bicycle, a mode shift from conventional bicycle to electric bicycle may consequently reduce an individual's overall health. It is not yet known if this concern will be realized. It is possible that electric bikes may extend someone's riding life and provide additional benefits in terms of increasing active transport options and the benefits of maintaining independent travel.

However, in countries with low rates of cycling participation, including the United States, United Kingdom, and Australia, it is more likely that an electric bike will offer a transport mode that will encourage more people to ride. Given the low proportion of people who cycle in these countries, the mode shift is likely to be from cars and public transport to electric bikes and this could result in substantial personal and community benefits.

Bicycle–Transit Linkages

Cycling and transit both contribute to improved health and environmental outcomes, as well as to reduce energy use and traffic congestion. Bicycle–transit linkages can help replace driving to and

from stations, expand transit's catchment area beyond walking distance, reduce the need to transfer among transit services, and attract both existing and new transit users. Bike-and-ride provisions are less expensive and more sustainable and socially equitable than park-and-ride facilities for cars. Coordination of cycling and transit includes bike parking at stations and transit stops, on-board space for transporting bicycles with travelers, bike rental facilities near transit stations, "complete streets" policies that promote bike routes near public transportation, partnerships that pursue cross-promotion of cycling and transit, and complementary car parking regulations and fees that limit space for automobiles at transit stations and create disincentives for driving.

Strategies to integrate cycling and transit vary globally, and implementation efforts generally have been increasing in recent decades. Coordination efforts in Europe and Japan began much earlier than in North America, reflecting differences in the overall levels of travel by bicycle and transit. There are currently an estimated 800,000 bike parking spaces at metro and suburban rail stations in Tokyo, where 20 percent of transit passengers cycle to stations, and 325,000 bike parking spaces at train stations in the Netherlands, where 39 percent of all rail passengers cycle to stations. In contrast, the entire United States has an estimated 38,000 bike-and-ride parking spaces, and just 3 percent of passengers currently access transit by bicycle.

Implementation of the integration strategies also varies geographically. For example, Japan and Europe have tended to focus on the provision of facilities at transit stations (bike-to-transit), which faces fewer capacity constraints, while North American efforts have prioritized onboard accommodations (bike-on-transit), which North American passengers prefer over leaving bikes at stations. Bike route networks are better connected to transit stations in Europe than in North America, where bike paths are more recreationally oriented along rivers and through parks. In general, the demand for bike-and-ride provisions continues to grow globally, and cities around the world are devoting more resources for both existing and new innovative approaches to support the integration of cycling and transit.

A range of cycling–transit integration strategies have been developed in recent decades. All of the strategies discussed below have been found to be

effective at increasing bike-and-ride travel as well as overall cycling and transit levels.

Facilities

The most common cycling–transit integration strategy globally is the provision of bike parking at transit stations. With this strategy, travelers leave their bicycles at the access station and rely on another bicycle or mode of transportation (often walking) at the egress station. In general, bike parking costs less than a tenth as much as park-and-ride facilities for automobiles on a per-passenger basis. There are many different types of bike parking, ranging from simple bike racks near bus stops to full-service bike stations, which are often located near major rail terminals. The degree to which bike parking is enclosed is a key distinction and relates to both sheltering from weather as well as security and theft prevention. The continuum ranges from open-air bike parking on sidewalks to guarded parking lots, bike cages and lockers, and full-service indoor bike stations. Open-air bike parking on sidewalks is the least secure and most exposed. Guarded bike parking lots deter theft but offer no protection from the weather.

Bike cages are typically unguarded restricted-access facilities and are often enclosed and incorporate surveillance cameras. They can be less secure than bike lockers, because anyone with access to the facility has access to all the bikes parked there. Boston, Massachusetts, and Portland, Oregon, are two U.S. cities that have deployed this strategy extensively. Many European and some Australian cities also have bike cages at transit stations.

Bike lockers are sturdy boxes that hold one or two bikes and are rented for hourly, daily, or long-term use. They provide more protection from weather and theft than open-air bike parking and bike cages but require more space and resources to construct and manage. Bike lockers in general are the most common form of secure bike parking in North America.

Bike stations offer the most secure and advanced bike parking at transit stations, with the greatest shelter from weather and mitigation of theft risk. They are staffed facilities offering a range of services, such as bike repairs and rentals, showers, and lockers, in addition to secure bike parking. In 2011, the Netherlands had 98 bike stations with space for 85,000 bikes, and Germany had 106 stations offering 32,000 spaces. North American cities with bike stations at

A bicycle commuter in Auckland, New Zealand, takes advantage of on-board bicycle storage to ride a small ferry in 2006. Facilities that make bicycle–transit linkages easier are more developed in parts of Asia and Europe than they are in North America. There are 800,000 bike-and-ride parking spaces alone in Tokyo, Japan, compared to only 38,000 in the entire United States.

that time included San Francisco, Washington, D.C., Toronto, Chicago, Minneapolis, Portland, and Seattle. Tokyo has advanced bike stations that allow the rapid automatic deposit and retrieval of bikes.

Provisions to take bikes onboard transit vehicles are typically in the form of front-end racks for buses, and racks, hooks or delineated spaces on trains. This strategy can reduce concerns about theft and weather exposure related to bike parking at transit stations, though onboard accommodations face more acute capacity constraints—bicyclists may be unable to board a bus with full bike racks or a train full of passengers or other bicycles. The paradoxical result is that onboard accommodations may be most constrained where cycling and transit are most popular. In general, bike racks are common in North America (with over 70 percent of American and 80 percent of Canadian buses equipped) and rare in Europe. Bicycles are typically permitted on

trains in Europe, North America, and Australia outside of peak travel hours.

Bike Rentals and Sharing

Bicycle rental programs at transit stations address many of the limitations of bike parking and onboard accommodations by enabling access to bicycles at both ends of a transit trip, reducing concerns about theft and weather exposure for personal bicycles parked at transit stations, and potentially rendering fewer bike-on-transit trips necessary. Three types of bicycle rental systems have been developed: (1) traditional single hourly or daily rentals requiring a transaction with an attendant, (2) automated hourly or daily rentals based on global positioning system (GPS) technology or membership cards, and (3) public bike sharing systems offering daily or long-term membership and providing access to a network of bicycles.

Bicycle rentals are most widely deployed in Europe, and traditional bike rentals are available at virtually all major Dutch, Danish, German, and Swiss train stations. In addition, several European countries have been leading innovators in the development of public bicycle-sharing systems. Bicycle sharing has evolved in recent decades from “White Bikes” (or “free bikes”) and coin-deposit systems to the information technology-based systems rapidly being deployed around the world today. Typically, bike-sharing fee structures encourage short trips of a half hour or less, and the systems are commonly designed to facilitate “first-mile/last-mile” connections with transit. There are currently approximately 140 public bike-sharing programs in 160 cities with more than 236,000 bicycles around the world.

Bikeways and Bike Lanes

Policies to coordinate bike paths and lanes with the location of transit stations and the operations of transit vehicles are critical for enabling travelers to access transit via cycling and interact with transit vehicles while cycling on the road. “Complete streets” policies have become important for designing streets that facilitate use by transit vehicles and cyclists, as well as automobiles. Cycling paths and lanes close to transit enable cyclists to use transit for planned trips, as well as trips arising from unexpected issues such as mechanical problems and inclement weather. In Europe, cycling networks are typically dense and focused on utilitarian destinations, thereby facilitating cycling for everyday travel needs. In contrast, coordination of paths and lanes in North America has been much more limited and routing has been more focused on recreational cycling.

Other Approaches

Partnerships that facilitate the cross-promotion of cycling and transit can include transit agencies and local jurisdictions, as well as bicycle and environmental advocacy organizations, and may be short-term or long-term collaborations. In North America, where both cycling and transit face less cultural acceptance and more social stigma and opposition, efforts to cross-promote both modes may be more effective at improving the public image of cycling and transit than individual efforts.

Deployment of complementary car parking regulations, fees, and policies is important as well. In

Europe, driver licensure is more expensive, gasoline taxes are higher, and free parking lots at transit stations are less common than in North America. When driving to transit stations is convenient and inexpensive, efforts to encourage travelers to access transit by cycling are less effective. Policies that limit the availability of car parking and charge fees for it at transit stations are important for effectively promoting cycling to transit.

Bicycling, Health and Recreational Aspects of

Bicycling has great positive effects on the physical and psychological health and recreational outlook of individuals and communities. The health and recreational aspects of bicycling and related activities are diverse and vary across culture, place, time, and other dimensions. New forms of bicycling recreation continue to emerge over time, and there are ebbs and flows of the popularity of a particular discipline

or activity. Similarly, health benefits of bicycling become apparent through new research. The capacity of bicycling to simultaneously fulfill multiple objectives, such as recreation, health, transportation, and mobility, is a major theme in understanding and assessing the benefits of bicycling. This becomes especially evident when comparing and contrasting bicycling with other travel modes.

Definitions

Alley cat. An informal bike race, originating in bike courier culture and often organized by messengers. There are several formats, most often involving checkpoints that may be revealed before the start or may be assigned one at a time as in a scavenger hunt. Racers carry a manifest that must be marked at each check station. There are no fixed routes, only checkpoints. Participants may be required to perform tasks or antics at a check station to have their manifest marked. Alley cats may take the form of a scavenger hunt–style point-collection race.

Bike building. The assembly of a bicycle. Most factory-built bicycles are shipped partially assembled and are finally assembled and adjusted by the retailer. High-end and custom bikes are often assembled from individual components by a bicycle shop or enthusiast/owner.

Bike polo. A sport derived and adapted from horse-mounted polo, originated in Ireland in the late 1800s. The earliest bike polo was played on grass fields, like conventional polo. Contemporary bike polo, which was popularized in Seattle in the late 1990s and spread globally, is played on asphalt or concrete and is known as hardcourt bike polo.

BMX. Bicycle Moto Cross, adapted from the “MX” abbreviation for motocross racing that inspired BMX riding and racing. BMX originated in Southern California in the 1970s with dirt track racing on 20-inch-wheel one-speed bicycles; there are also BMX cruiser bikes with 24- or 26-inch wheels. BMX tracks often have a starting gate and a high-speed serpentine course with various types of jumps and berms that racers traverse in a sprint to the finish line. Racers compete in qualifying rounds known as “Motos” leading up to the “Main” race. BMX stunt riding has become more popular than racing. BMXers ride skate parks, plywood ramps, and found

street obstacles as well as constructed trails and dirt jumps. Many stunts involve technical maneuvers while airborne. BMX shares terrain, some tricks, and cultural elements with skateboarding.

Chopper. (1) any sort of garage-modified bicycle; (2) a bike with a relaxed head angle and extremely long fork, analogous to a motorcycle chopper.

Ciclovía/open streets events. These are planned and organized celebrations of nonmotorized and pedestrian travel. During these events, streets are closed to motor vehicles for the day or for several hours to allow citizens to walk, pedal, and skate in an ephemeral nonmotorized space. These events may include and be focused around a bicycle parade. Seattle’s Bicycle Sundays, beginning in 1965, and Bogota’s Ciclovía, operating since 1978, are two of the longest running Open Streets events.

Critical mass. A nonorganized event, occurring the last Friday of every month during the evening rush-hour, typically beginning at 6:00 P.M. Riders congregate and make a spontaneous, nonpermitted bicycle parade through the city, generally without a preplanned route. This 20-year-old happening, which has operated as an emergent phenomenon in over 450 cities globally, began in San Francisco and quickly spread to other cities in the United States and abroad. It is simultaneously a festival, a celebration of cycling, and a protest against poor existing conditions for bicycle riders.

Cyclocross. Also known as CX or “cross” racing, cyclocross is a form of off-road racing, primarily done on 700c wheel drop bar–equipped bicycles originally derived from road racing bikes. Cyclocross originated in western Europe as a form of winter training for bicycle racers. In this fall and winter sport, racers ride off-road over rough terrain doing multiple laps on a short, technical course.

Frame building. The construction of a bicycle frame. Metal frames are typically tungsten inert gas (TIG) welded, fillet brazed or lugged, and brazed from steel, aluminum, or titanium. Metal bicycle frames have largely been built from materials ranging in quality from mild steel to high-strength super alloys of steel, aluminum, and titanium, though magnesium has also been used.

Since the mid-1990s, aluminum frames have become much more common. Carbon fiber has become the material of choice for racing and high-performance bikes in many disciplines of cycling and has become increasingly common.

Gran fondo. “Large Ride” from the Italian. Also known in French as *Cyclo sportive*; a large mass-start social ride for riders of varying fitness and skill. The events are noncompetitive but they do have a maximum completion time.

Lowrider. A bicycle with low bottom bracket, short cranks, and a low saddle; often decorated extensively and elaborately in the fashion of a lowrider car. Lowrider bikes often have a springer fork, a banana-type seat, and very high-rise “ape hanger” handlebars and ample chrome plating. They may include mirrors and other accessories, faux fuel tanks, or other motorcycle-inspired adornments.

Tallbike. A bicycle that is significantly taller than a typical bicycle, typically made from two bicycle frames welded, brazed, or bolted one atop the other. The rider cannot straddle the top tube of the frame with his/her feet on the ground. Presently, these bikes are made and used for hobby and recreation. Historically, lamp lighters used purpose-built tall bicycles to light gas street lamps.

Touring. Bicycle touring is a pastime of traveling by bicycle and takes many forms. Self-supported overnight and multiday trips are popular, as are lightweight “credit card tours” on which riders pay for accommodations and prepared food instead of carrying camping and cooking gear. Van- and crew-supported bike tour packages are also popular, and there are a number of firms specializing in supported tours, local and international. Gravel road and off-road touring continues to gain popularity as do all forms of bicycle touring. Bike touring has proven to be a great boon to some rural economies along popular bike routes. Purpose-built touring bikes are popular and have their advantages, though it is feasible to tour on many different types of equipment.

Randonneuring. An organized, noncompetitive, self-supported, long-distance bike-riding activity. Randonneurs often ride long distances in a single

push, through the night, without significant sleep breaks. The organized rides take on different names with varying length. For example, a brevet is 200 kilometers. These rides require riders to reach checkpoints called controls. Riders are required to complete each segment within a specified time range. Fast riders are made to wait at controls and riders moving too slowly are disqualified. In terms of frame geometry, a randonneuring bike is between a road-racing bike and a touring bike and is designed to carry a light load with small racks to support dedicated bags. They often include integrated generator-powered lights and fenders. While dedicated randonneuring bikes are popular, other types of bikes can be adapted for the purpose.

Recreation. An activity done away from work time that is refreshing or fun. For example, professional bike racers are not recreating while they are training or racing, though they may be while riding with their families.

Safe Routes to School (SRTS): An international movement promoting active transportation to schools for elementary and middle school students. The programs focus on walking and biking safety and encouragement. SRTS is based on the principles of the “Five Es”: education, encouragement, evaluation, engineering, and enforcement. The program originated in Denmark in the late 1970s and the first Safe Routes program in the United States was in the Bronx in 1997. In 2000 the U.S. Congress funded two pilot programs in Marin County, California, and Arlington, Massachusetts, for the 2000–01 school year. In 2005 Congress formalized the program and provided a five-year funding package as part of the SAFETEA-LU legislation.

Velodrome Track: Track riding and racing is done on a velodrome, indoor or outdoor. A velodrome is a smooth, hard-surface race course for bicycles. Velodromes are typically ovals with banked corners and are constructed of wood, concrete, or asphalt. Racers compete on fixed-gear bicycles, which do not freewheel, without brakes. As with other forms of bike racing, there are several disciplines of track riding, including various individual and team events.

Wheel building: The assembly of a wheel from its component parts, including rim, hub, spokes, and

spoke nipples; the assembly steps include lacing, tensioning truing, stress-relieving, and final tensioning.

Health Aspects of Bicycling

While most physical activity is beneficial to the participant, bicycling offers a multitude of benefits. The health impacts of biking are not only physically beneficial but can also holistically improve psychology, emotion, and community. Bicycling is compelling in part because it is so versatile and can achieve many goals and purposes, often simultaneously, and while it can be, it does not need to be viewed as sport. Bicycle riders can be subject to acute and chronic injury, though these are largely avoidable with due care and safe practices.

The physical activity benefits of biking are many. Bicycling offers a balance of muscular and cardiovascular exercise; it is a non-jarring and low-impact workout with a low risk of overuse injuries. Bicycling has benefits for many systems of the human body, including the musculoskeletal, immune, nervous, endocrine, digestive, pulmonary, and cardiovascular systems. The benefits of bicycling for these organ systems lead to improved outcomes for strength, flexibility, body mass, blood sugar, cholesterol levels, blood pressure, agility, and muscle tone. Different disciplines of bicycling place different demands on the body. For example, mountain biking and BMX riding demand more from the upper body muscles than does road riding.

Most bicycle riding takes place outdoors, which provides significant health benefits, including access to fresh air and sunshine, opportunities for spontaneity, and social interaction. The vitamin D production in human skin that occurs with sun exposure is a notable health benefit of biking, but solar rays also carry harmful ultraviolet and infrared light that can lead to skin and eye damage; sun protection for eyes and skin is important.

Bicycling can be especially good for joint health. For example, cycling strengthens the muscles that support the knee joint, in particular, the *vastus medialis*, which helps control the *patella* (kneecap) and can help correct knee problems. In contrast, most disciplines and forms of bicycling are not particularly good for bone health because there is not enough impact and weight bearing to improve bone density. This can be a concern for those with low bone density and high mileage bike riders who do not engage in other physical activities for cross training.

Psychological and Social Health Benefits

Bicycling is reported by participants and researchers alike to have great positive effects on the mood and psychological state of participants. Bicycling is sometimes referred to as the happiest mode, and this notion is supported by recent research. Bike riding can make people happier, and in particular, bicycle commuters arrive at work with a better attitude than their car-driving and bus-riding counterparts. Bicycling is good for self-image, mood, emotional health, happiness, and self-actualization.

Commute travel is a considerable source of anxiety for many, so the benefits of bicycle commuting can be especially dramatic as seen in contrast to other travel modes. All types of bicycling can also offer mental and physical health rewards. While there are many physiological health benefits of bicycling, the psychological benefits should not be overlooked. Bicycling is good for the mood and can help focus the embodied mind. Bicycle riders receive a measure of psychic income each time they ride their bike; this may come in the form of a feeling of well-being, improvement in mood, exhilaration, autonomy, or self-reliance.

Bicycling is good for individual health and community health. The ecological, land use, and transportation benefits of bicycling help improve community health in objective and measurable ways. Bicycling also offers opportunities for social interaction within a community, beyond what is possible between drivers of motor vehicles. Increases in bicycle ridership have been observed to improve road safety for all road users. One of the clear benefits to the broader community of bicycling is the reduction in fuel and power consumption and air pollution created by bicyclists forgoing motorized travel. Under the rubric of community health, access to active transportation can easily be seen as a public health and social justice issue. Biking makes accessibility and mobility better, and communities that lack opportunities for bicycle and pedestrian travel are not serving the needs of their residents.

In addition to offering many health benefits, bicycling also presents some risk of acute and chronic injury. The majority of acute bicycling injuries are the result of falls caused by a rider losing control of his/her bike and are, therefore, avoidable. Chronic injury from repetitive stress can be avoided through proper fit and good ergonomics. To avoid these chronic injuries, the size of the bicycle should

match the size of the rider, and the relationship of the saddle, handlebars, and pedals of a bicycle should be carefully adjusted for the individual.

Recreational Aspects

Recreational bicycling is often associated with amateur racing, group rides, touring, and large organized rides. These are all popular and important forms of recreational bicycling, but there is much more to bicycle recreation. As bicycling becomes increasingly popular as an everyday activity, there are corresponding increases in organized, noncompetitive events that are focused on the conviviality of the experience and less oriented toward competition and rankings, such as Gran Fondos and Ciclovía events. Additionally, the material cultures of bicycling are becoming increasingly visible in mainstream culture, on and off the bike.

There are many diverse and emerging forms of bicycle recreation. Social change and trends lead to ebbs and flows in the popularity of a discipline or subdiscipline of bicycling. There are also many bicycle and bicycling-related recreational activities that do not necessarily include riding bicycles, such as bicycle repair and maintenance, assembly and production, and bike art, which can include creation and display of photography, painting, video, film, sculpture and furniture made from bike parts.

Utilitarian and commute bicycling are often thought of as separate from recreational bicycling, but a given trip can be understood to fulfill multiple purposes—recreational and utilitarian. Not every bicycle trip has a recreational element but many do, even if they also have a utilitarian purpose. Utilitarian bicycle trips simultaneously deliver the health benefits of exercise and allow utility bicycle riders to skip gym workouts and other workout routines.

Bikeways/Bike Lanes, Road Design Issues of

Bikeways, or bike lanes, are dedicated road infrastructure for cycling. Their need derives directly from the difference in travel speed of bicycles and motorized vehicles such as cars, buses, and motorcycles. The choice of the type of cycling infrastructure to be implemented in a road segment is first and foremost connected to the desired and/or planned travel speed for a certain road segment. The basic goals of the design of cycling infrastructure are to reduce delays or diversion and to improve cycling safety.

Bikeways are one of several ways of improving cycling conditions in an urban area, and indeed other priority measures should be taken as well. By order of priority, the following measures should be applied: reducing traffic volume, reducing traffic speed, junction treatment and traffic management, reallocation of carriageway space, building/improving bikeways, and converting footpaths to shared use. As a general principle, removing pedestrian space should not be an option when creating cycling space. These measures should also be combined when designing a cycle network, once the network can be made of different typologies along the route.

Network Requirement Principles

Cycling infrastructure must be designed in accordance with five main requirements, which are coherence, directness, safety, comfort, and attractiveness:

Coherence. Cycling infrastructure must be complete, creating a coherent whole. Cycling infrastructure should guarantee connections between main origins and destinations, through a coherent, whole system, giving opportunity to all people to go somewhere by bicycle. Safe bicycle parking at origins and destinations directly contributes to coherence. Other key elements are signaling and marking, consistent quality of the infrastructure, and ensuring that different routes are available.

Directness. Cycling infrastructure must allow cyclists to reduce travel time and travel distance, so cyclists can choose the most direct route, minimizing detours as much as possible. Factors that can contribute to reducing travel time include traffic lights, crossing of busy main roads, and detours. Design elements with a clear influence are cycle shortcuts between roads, allowing two-way cycle traffic on one-way roads (contraflow lanes), and implementing two-way cycle lanes on both sides of main roads to avoid crossings.

Safety. Cycling infrastructure should ensure the safety of cyclists and of other road users. Cyclists are vulnerable road users as they do not have external protection and show considerable differences in terms of mass and speed to motorized modes. Visibility is a main issue of cycling safety, and in dark or rainy weather cyclists' vulnerability increases due to the decrease in overall visibility.

Design is paramount to ensuring cycling safety, avoiding encounters with fast-moving motorized traffic. Important elements are the implementation of traffic calming measures, minimizing the need to travel along dangerous roads, providing clear signage and indications of routes, reducing the number of traffic solutions, reducing speed at junctions, and separating different vehicles where speed reduction is not possible.

Comfort. Cycling infrastructure should allow a comfortable cycle ride. The average urban bicycle has no suspension, and so a smooth surface should be offered in order to provide comfort. Poor surfacing,

bottlenecks, and shortcomings in infrastructure are a source of nuisance and delays. Minimizing chance of stopping and annoyance caused by other traffic and weather should be ensured.

Attractiveness. Cycling infrastructure should fit well with surroundings. In order to increase attractiveness, it is extremely important to listen to cyclists' complaints and provide adequate answers to them. Attractiveness is also related to social safety, as cyclists feel safer in busy places.

All these principles are important when designing cycling infrastructure; however, different priorities may be given in accordance with the different users' needs. A clear indication of poorly conceived and designed cycling infrastructure is its disregard by cyclists, riding on the road instead, mixed with other traffic.

Types of Cyclists

Different cyclists have different abilities to cycle, especially with regard to travel speed and willingness to mix with motor traffic. It is common to consider five different categories of cyclists:

- *Fast commuter:* A highly confident cyclist, willing to mix with motor traffic in order to reduce travel distance
- *Utility cyclist:* A confident cyclist, but may require some segregation on busy junctions and on segments with high-speed and/or high-volume motor traffic
- *Inexperienced and leisure cyclist:* Values safety at the expense of directness, searches for routes with less traffic
- *Children:* Safety is paramount; segregated routes are normally required for access to schools, even if on-road solution exists; additional width should be considered in order to accommodate parents escorting children side-by-side
- *Users of special equipment:* Cyclists with trailers, tandems, and tricycles require additional width for riding and overtaking

In order to attend to all users' needs, it may be necessary to implement dual networks, one with more segregation from motor traffic at the expense of directness, dedicated to inexperienced and

leisure cyclists, children, and other users with special equipment.

Types of Bicycle Facilities

Cycling facilities can take the form of cycle tracks or paths (bikeways), and cycle lanes. The main difference between them is the type of segregation: cycle tracks or cycle paths are physically segregated and cycle lanes are visually segregated. Nevertheless, cycling is possible and common on roads without dedicated cycling infrastructure, if traffic speed is slow and traffic flow is small.

Cycle tracks take more space than cycle lanes but provide better protection to cyclists, facilitate overtaking by cars, and make cycling less affected by congestion. However, if they cannot be properly applied in intersections, all these advantages are lost and accidents can increase. Other disadvantages include loss of freedom to cyclists and less awareness from drivers who tend to speed more. Segregation can be accommodated by a strip of grass, a curb, setting the lane at a different level, or putting in other elements like a line of trees, posts, or other barriers.

Cycle lanes are easier and less expensive to implement, but they require slower traffic speed from motorized traffic in order to provide adequate safety to cyclists. They are also hard to implement on roads with large volumes of traffic or heavy vehicles. Cycle lanes make cycling visible to drivers and express equality of all road users, contributing to raising awareness of cycling. They should be the most common solution in cities, together with speed reduction techniques.

Two basic criteria should be used in order to choose the right type of cycling facility: the 85th percentile speed and traffic flow. Cycle tracks or cycle paths are recommended for segments with speeds higher than 30 miles per hour (mph) (50 kilometers per hour [km/h]) or more than 10,000 vehicles per day (vpd). If the 85th percentile speed is below 20 mph (30 km/h) and traffic flow is lower than 6,000 vpd, no dedicated cycling infrastructure is needed, as cycling is possible mixed with traffic. Cycle lanes are recommended for intermediate situations.

Besides these general criteria, in streets with slow traffic, increasing the width of the near-side lane can make a cycle lane unnecessary, as it increases clearance when overtaking. Likewise,

on high traffic streets with many side roads, bus stops, and other curbside accesses, cycle lanes may be of little use, making it preferable to reduce traffic speed and increase lane width rather than provide cycle lanes.

On streets with significant gradient, a cycle lane is extremely beneficial in the uphill direction, but it can make cycling conditions worse in the downhill direction, as speed differential going down can be irrelevant. In these cases, it is often preferable to have a wide single bike lane going up rather than to have two narrow lanes in both directions.

On one-way streets, contraflow cycle lanes should be considered if they could be safely accommodated on the street, as cyclists tend to ride these streets both ways in order to increase directness.

General Design Parameters

In order to ride comfortably and safely, a cyclist needs space that depends on the cyclist's dynamic envelope, the clearance to fixed objects, and the distance from other traffic. Increased speed differential between cyclists and other motorized traffic requires additional separation.

Dimensions of Cycles

A typical bicycle is 6 feet (180 centimeters [cm]) long and 2 feet (65 cm) wide, but other, nonstandard cycles should also be considered when designing cycling infrastructure. Minimum turning circles for a typical bicycle is 2.8 feet (85 cm) inner radius and 5.4 feet (165 cm) outer radius, but it depends on the ability of the cyclist to turn at low speed. Tandems, tricycles, and trailers increase both length and width of the cycle, and so additional width and turning circles should be considered—for a tandem, the minimum values are 7.4 feet (225 cm) inner radius and 10.3 feet (315 cm) outer radius.

Dynamic Envelope

Cyclists do not ride in a straight line. In order to sway the bicycle, cyclists need a space larger than their shoulders' width. To keep a straight line and to balance the bike without a conscious effort, cyclists need to ride at a speed of 7 mph (11 km/h) or greater. At this speed, cyclists need 8 inches (0.2 meters [m]) additional shoulder width. Below this value deviation increases, reaching typically 2.6 feet (0.8 m) at 3 mph (5 km/h). A dynamic envelope of 3.3 feet (1.0 m) width should be considered.

Distances to Fixed Objects and Other Cyclists

When passing fixed objects, cyclists need additional space that varies in accordance with the height of the object. Curbs less than 2 inches (50 mm) high require 10 inches (0.25 m); curbs over 10 inches require 1.6 feet (0.5 m); signposts, columns, etc., require 2.5 feet (0.75 m); and continuous features such as walls require 3.3 feet (1.0 m).

In order to allow cyclists to pass each other, a separation of at least 1.5 feet should be provided between the dynamic envelopes of each cyclist, requiring a minimum width of 8.2 feet (2.5 m) for a two-way cycle track.

Safe Passing Distances

The safe passing distance between cars and cyclists should increase with the driving speed. At 20 mph (30 km/h) cars normally pass leaving a 2.8 foot (0.85 m) clearance space, which may be stressful and uncomfortable to some cyclists. Minimum suggested passing distances are 3.3 feet (1.0 m) for cars passing at 20 mph and 5 feet (1.5 m) for cars passing at 30 mph (45 km/h).

Cycle Lanes Design

Cycle lanes are intended to improve cycling conditions, but poorly designed infrastructure can worsen cycling conditions. Cycle lanes are needed whenever the speed differential between cyclists and motorized traffic is high. Therefore, slowing traffic speed can be as efficient as cycle lanes in increasing cycling conditions. As mentioned above, where 85th percentile speed is less than 20 mph (30 km/h), cycle lanes are generally not necessary.

Cycle lanes can be mandatory or advisory. Mandatory cycle lanes are marked by a continuous white line and are to be used exclusively by bicycles. When these mandatory cycle lanes cross side roads, advisory cycle lanes should replace them in order to allow other vehicles to cross. Although not necessary, these mandatory cycle lanes should have double no-parking lines alongside the curb in order to discourage motor vehicles from parking on the lanes. Advisory cycle lanes are normally marked by discontinuous white lines and are adequate to guide cycle traffic in large and/or complex junctions. Advisory cycle lanes are also adequate to raise driver awareness of the presence of cyclists and are recommended on streets with ample carriageway width.

As a general rule, the minimum recommended lane width is 6.6 feet (2 m), as it allows cyclists to overtake other slower cyclists, to remain in the cycle lane when checking for traffic, and to avoid curb-side drainage grates and debris. On streets with significant traffic or traveling at more than 40 mph (60 km/h) this is the recommended minimum width. On streets with a 30 mph (50 km/h) speed limit a minimum width of 5 feet (1.5 m) is normally accepted. It is acceptable to reduce lane width to 4 feet (1.2 m) for cycle feeder lanes to advanced stop lines (bike boxes, see below). Cycle lanes narrower than 4 feet are not acceptable in any case, as they cannot accommodate tricycles or bicycles with trailers.

If the cycle lane is located in a street with allowed parallel parking, there is need to implement a buffer zone of between 1.6 foot (0.5 m) to 3.3 foot (1 m) widths alongside parking, in order to accommodate the additional space required to load and unload the car.

Two-way cycle lanes are not generally recommended and should be avoided because they are normally confusing to car drivers and can be significantly dangerous when crossing a road. When a two-way cycle lane crosses a road, some of the cycle traffic will present itself as contraflow to the car driver, increasing the probability of an accident. Nevertheless, in some specific segments they can be applied, but a physical segregation should be implemented (a curb or other element). Examples are dedicated cycling underpasses or bridges of major junctions or leisure cycle lanes along parks and other green areas. Another example is using the central median of the street to locate a two-way cycle lane. The minimum width of a two-way cycle lane is 8.2 feet (2.5 m).

Intersections

Intersections are specific cases in a cycling network that require particular attention and detail—if poorly designed, they can contribute to accidents, and 70 percent of accidents involving cyclists occur in intersections. Visibility and safety are paramount.

For signalized intersections, a common, safe and affordable solution is the introduction of advanced stop lines (ASL) with a cycle feeder lane. This solution enables cyclists to overcome motor vehicles on the approach to the junction and to position themselves in the right place for their intended maneuver while the signal is red. An ASL is made up of a stop

A bicyclist stopped at an intersection with a two-way bike lane in Lille, France. Two-way bike lanes are recommended only for limited situations and normally require 8.2 feet (2.5 m) of space.

line for motor vehicles, an additional stop line for cyclists near the signal, and a lead-in (feeder) cycle lane. The area between the two stop lines forms a reservoir for waiting cyclists and should be between 13 to 16.4 feet (4 and 5 meters) deep. Lead-in lanes can be mandatory or advisory and should have 4 foot (1.2 m) minimum width. Non-nearside lead-in lanes are extremely useful when the nearside lane is dedicated to vehicles turning right. In this case, they should be marked as advisory lanes and, as they will be located between two lanes of moving traffic, a minimum width of 6.6 feet (2 m) is recommended. Applying a colored surface on ASL and feeder lanes is useful to increase visibility.

An alternative to ASL is commanding the left turn in two stages. In this case, left turns are not

allowed and cyclists have to move forward and wait at the stop line of the perpendicular road in order to turn left. This solution increases safety, but it also can increase overall travel time.

Raised tables are extremely useful in intersections as they reduce overall traffic speed. Raised tables that occupy the entire intersection can be used at priority junctions, making separate cycle facilities unnecessary.

Roundabouts

Roundabouts are special cases of intersections in which the risk of a cyclist accident is higher. Due to the process of motorized vehicles entering and leaving the roundabout, riding near the curb puts cyclists in the most dangerous position. A main improvement in the negotiation and ride of a roundabout by a cyclist is overall traffic speed reduction.

Cycle lanes on roundabouts are indeed not proven to contribute to an increase in safety. If present, they should occupy a position in the center of the carriageway and be accompanied by speed reduction measures. Redesigning entry and exits lanes to a more radial than tangential position is also recommended. In large roundabouts, alternative routes or the introduction of peripheral segmented cycle tracks should be considered, with signalized crossings on the roundabout arms.

Biodiesel

Scarcity of known petroleum reserves and growing international concern with regard to climate change have resulted in the search for renewable and economically viable sources of alternative energy for transport. Biodiesel in particular is a type of biofuel that has been in the forefront of such alternative technologies, even though the extent to which it meets both the aforementioned criteria in practice is being increasingly questioned.

Biodiesel has received significant attention due to its similarity to conventional diesel in terms of energy content and chemical structure. It is produced from the reaction of vegetable oils or animal fats with an alcohol. Producing biodiesel from such sources is not a new process. In the 1900s, Rudolf Diesel had actually designed the original diesel engine to run on peanut oil. Low fossil-fuel prices prevented the further development of biofuels in general for the most part of the 20th century, but interest in commercial production was stimulated as a result of the two oil crises in the 1970s.

Biodiesel can either be used directly or as a blend with petroleum-based diesel. The level of blending is designated "Bxx," with "xx" indicating the amount of biodiesel in the overall blend. For example, various concentrations are currently present in the market, such as pure (B100), blends (B20–B30), additive (B5), and lubricity additive (B2).

Feedstocks

There are various raw materials that can be used as feedstock for biodiesel production. To begin with, edible vegetable oils are the most common source. For instance, rapeseed is the most important feedstock in the European Union, palm oil in Malaysia, and soy in Brazil and the United States. The fact, however, that neat edible oil competes with food supply has resulted in biodiesel from such sources becoming increasingly embroiled in controversy.

Consequently, using nonedible oils so as to avoid conflict with food consumption has emerged as an attractive policy option. *Jatropha*, castor, and rubber seed serve here as representative examples. *Jatropha* in particular was once thought of as the "miracle crop" for the production of biodiesel, given that *Jatropha* is a drought-resistant, nonedible perennial that can be planted on marginal land and requires limited water or agrochemical supply. So

far this potential has not been realized, as there are still large knowledge gaps that need to be addressed before fully commercializing *Jatropha* oil.

Waste oils, grease, and animal fats can also be used as feedstock for biodiesel production. One of the benefits of relying on such sources is that doing so eliminates the environmentally damaging practice of having to dispose of them. Yet developing the requisite collection infrastructure and dealing with logistics and quality control issues can be major challenges, especially with regard to waste oils and grease. Relying on animal fats poses less of a hurdle, given that the slaughter industry is generally well managed in such respects. There is, however, a bio-safety concern that needs to be taken into account, as contaminated animals could potentially be the source of animal fats.

Finally, algae has been receiving growing attention in terms of biodiesel production as it does not impact food production and has a far superior yield per hectare over conventional oil crops. Producing algae to harvest oil for biodiesel has not been undertaken on a commercial scale due to high production costs and the several scientific uncertainties that still need to be addressed.

Advantages and Disadvantages of Biodiesel

Biodiesel has a number of technical advantages compared to petroleum diesel fuel. To start with, it runs well in unmodified conventional engines and, as a result of its better lubricating qualities, it actually prolongs their lives, thereby reducing the need for maintenance. In addition, storage, transportation, and distribution to end users are identical to those of fossil diesel. Finally, biodiesel is safer to handle, as it is less toxic, more biodegradable, and has a high flash point compared to petroleum diesel fuel.

Regarding its emissions profile, the use of biodiesel in conventional diesel engines provides substantial reductions in emissions of inter alia carbon monoxide, sulfur oxide, unburned hydrocarbons (HC), and polycyclic aromatic hydrocarbons (PAHs). In addition, emissions of carbon dioxide are also significantly reduced, which is quite important given that climate change is considered the most pressing global environmental concern. Regarding nitrogen oxides, the literature is currently divided as to whether biodiesel results in an increase or decrease of their emissions.

Turning to technical disadvantages, the main problem associated with the use of biodiesel concerns poor cold-starting performance, as the fuel begins to gel at low temperatures. An equally important drawback concerns biodiesel's higher price compared to fossil diesel. This is due to high feedstock price, as the cost of raw materials accounts for about three to four quarters of the total production cost of biodiesel. Other major technical disadvantages include lower energy content, higher viscosity, injector coking, higher cloud and pour point, degradation of fuel under storage for prolonged periods, and others. Apart from technical disadvantages, there are also complications with regard to the sustainability of biofuels, which are outlined in the following section.

Biodiesel and Sustainable Development

The production and consumption of biofuels in general and biodiesel in particular have been met with a number of criticisms, namely, that they do not contribute to all three dimensions of sustainable development (society, environment, and economy). Some of the main criticisms are outlined below.

Starting with social sustainability, criticisms here concern the fact that biodiesel production does not take into account its impact on food prices and production. More than 95 percent of biodiesel production relies on edible oils, causing concern that large-scale biodiesel production could potentially destabilize the global food supply-and-demand market. There is currently a high degree of skepticism in the literature as to whether arable land should be used to grow biodiesel feedstock instead of food.

Turning to environmental sustainability, the worldwide expansion of oil-crop plantations to meet increased biodiesel consumption has been held responsible for widespread deforestation and ecosystem degradation in countries like Brazil, Thailand, Indonesia, and Malaysia. As a result, releasing carbon that has been locked away for thousands of years could therefore actually accelerate the effects of climate change.

Closing with economic sustainability, tariffs and subsidies are the two main mechanisms governments generally use in order to support their national biofuels industries. Such support measures, however, distort international trade by hindering imports of biofuels that are cheaper and far

more energy efficient. For example, biodiesel production in the European Union is not profitable without heavy subsidization. In addition, European Union biodiesel production is based on rapeseed, a feedstock considerably low in energy per hectare and in greenhouse gas savings. Support mechanisms therefore entail promoting biofuels that are often more expensive and far less energy efficient compared to their counterparts in tropical countries, for example, Brazilian sugarcane-based bioethanol.

Biodiesel Policies Around the World

Starting with the European Union, in excess of three-quarters of the demand for biofuels is met by biodiesel. The European Union is by far the world's leading producer. Ethanol accounts for some 20 percent. So far, the European Union has adopted two directives on biofuels. The first, the Biofuels Directive of 2003, contained a set of indicative targets for biofuels (2 percent by 2005, rising to 5.75 percent by 2010). Only seven member states (Germany, Sweden, France, Poland, Austria, Portugal, and Slovakia) have met the 5.75 percent figure, with the European Union overall having achieved 4.7 percent in 2010.

The second directive, the Renewable Energy Directive of 2009, contains a mandatory 10 percent biofuels target to be reached by 2020. This 2009 directive also contains (following widespread criticism from nongovernmental organizations) a number of sustainability criteria on the production and use of biofuels in the European Common Market. To begin with, the directive stipulates that biofuels must emit a minimum of 35 percent less greenhouse gas than the fossil fuels they replace. This percentage is set to rise to 50 percent in 2017. In addition, the sustainability criteria also stipulate that biofuel feedstock is not to be derived from primary forests, lands with high biodiversity value, protected territories, and carbon-rich areas.

In Brazil, ethanol production for transportation purposes has a long history, going back to the 1970s. However, the Brazilian government launched in 2004 the National Biodiesel Production and Usage Program (PNPB) in order to encourage the introduction of this biofuel into its energy mix. In the initial stages, refiners and distributors were adding 2 percent biodiesel to diesel. The PNPB proved to be quite successful, with biodiesel production

more than tripling between 2005 and 2010, making Brazil the second-largest biodiesel producer worldwide. As a result, the Brazilian government decided in 2010 to promulgate B5 as the mandatory blend. According to the PNPB, palm oil in the north, castor oil in the northeast, and soy and other crops in the remaining regions should comprise the preferred feedstock.

Special note should be made of the fact that one of the aims of the PNPB is to foster social inclusion through the generation of income for small producers. A Social Fuel Seal certificate is therefore awarded by the government to biodiesel producers who inter alia purchase a minimum percentage of feedstocks from family farmers and provide them with technical assistance.

The biodiesel industry in the United States is much younger and smaller compared to that for ethanol. Even so, biodiesel production and consumption have increased steadily over the years. As a result of its relatively low price, soybean oil is the most commonly used feedstock, accounting for over 50 percent of national production.

The U.S. Environmental Protection Agency (EPA) in 2010 established the so-called Renewable Fuels Standard (RFS2). This applies only to biofuels and mandates the consumption of a certain amount of biofuels per year until 2022. For example, the EPA had required that 800 million gallons of biodiesel were to be consumed across the United States during 2011. This figure went up to 1 billion gallons with regard to 2012, while the figure released for 2013 by the EPA was 1.28 billion gallons. With regard to sustainability, the RFS2 requires that biodiesel must demonstrate greenhouse gas emissions savings over its life cycle of 50 percent per gallon relative to petroleum-based diesel fuel.

Conclusion

Biodiesel as a fuel is much less polluting than petroleum diesel, achieving much lower emissions of almost every pollutant: carbon dioxide, particulates, carbon monoxide, and others. Biodiesel production, however, has been linked to unsustainable practices across the world, raising doubts with regard to the extent it can contribute meaningfully toward sustainable development.

Biofuels

Biofuels for transport are liquid or gas renewable energy sources that are produced from biomass and can be used as a substitute or blend for petroleum fuels. Once thought of as a viable green alternative, the debate today over biofuels provokes strong responses from people on both sides, as experts, nongovernmental organizations, and corporate actors are sharply divided concerning their sustainability.

Contrary to general belief, biofuels for transport have been in use since the late 19th century, even though large-scale industrial production is a more recent development. The first national-level program was launched in 1975 in Brazil, with ethanol being produced from sugarcane. The United States soon followed suit, using corn as the prime feedstock. Today, these two examples have been followed by the European Union, India, China, Thailand, and several others around the world. While several different varieties of biofuels are in the market, the only ones that can be currently supplied in adequate amounts are bioethanol and biodiesel. The former is based on crops that are high in either sugar (sugarcane or sugar beet) or starch (maize and corn). The latter is based on plants that contain high amounts of vegetable oil, such as soybean or oil palm.

Types of Biofuels

Promotion of biofuels has been supported worldwide for a wide range of reasons, namely, climate change mitigation, energy security concerns, and rural development stimulation. In terms of main producers, Brazil and the United States account

A technician at the U.S. Department of Energy's Argonne National Laboratory in April 2010 compares bacteria samples growing on media containing two different antibiotics. The bacteria was being studied for possible use in biofuel production.

for approximately two-thirds of global ethanol supply, while the European Union (mainly Germany, France, and Italy), Argentina, and the United States are topping the list with regard to biodiesel.

Biofuels from food sources are collectively known as first-generation biofuels. In order to avoid competition with food production, developing second-generation biofuels has been increasingly viewed as a more attractive option, as these are produced from inedible sources, such as woody crops, energy grasses, or even agricultural and forestry residues. However, unlike the easily processed first-generation biofuels, the complex substances found in the woody or inedible tissues of plants are much more challenging to chemically process and convert to energy with currently available methods. Consequently, several technological breakthroughs are still required for second-generation biofuels to become commercially viable. The same is true of third-generation biofuels, which are based on marine algae and seaweeds. A substantive amount of further research and development is required

before establishing an economical industrial-scale production of algal biofuels.

Sustainability of Biofuels

In what constitutes a classic example of policy running ahead of science, several governments rushed to set up biofuels programs without having carried out in advance a thorough assessment of all the pros and cons associated with biofuels commercialization. First-generation biofuels in particular have become embroiled in some of the most highly contentious debates on the current international sustainability agenda, given their links to energy security, transport, trade, food security, land use, and climate change concerns. A number of the most controversial sustainability complications of biofuels are outlined below.

To begin with, there has been growing concern with regard to the energy efficiency of biofuels. It should be noted at this point that biofuel sustainability depends on the type of feedstock crop used, the cultivation methods, and processing techniques. On one hand, for example, a growing body of research has recognized sugarcane-based ethanol as the most energy-efficient and price-competitive biofuel worldwide. On the other hand, palm oil biofuels have been held responsible for causing damaging deforestation and reducing biodiversity, whereas study results have consistently highlighted the poor energy efficiency properties of corn-based ethanol.

Another major environmental concern with biofuels production is that their increased production and consumption could cause considerable land use change (LUC), both direct (dLUC) as well as indirect (iLUC). In particular, measuring iLUC (e.g., biofuel plantations replace pasturelands, which replace forests) is scientifically quite challenging, with consensus as to how to monitor and control it being currently lacking. Scholars have argued, for instance, that even carbon savings from Brazil's highly energy-efficient sugarcane-based biofuels could be offset if iLUC changes were factored in, especially those pushing the rangeland frontier into the Amazonian tropical forest region.

Finally, biofuels use has been criticized for not taking into account the impact of biofuels on food prices and availability. The argument here goes that dedicating a sizable part of the harvest production to biofuels could potentially drive food prices up and lead to food shortages and urban

riots. As a result of alarming increases in food prices between 2007 and mid-2008, several riots erupted in several developing countries around the world, including Mexico, Haiti, Yemen, and Zimbabwe. The literature is currently divided as to whether biofuels are to be held responsible, with some viewing food price increases as a direct outcome of enhanced biofuels consumption, while others mainly attributing them to factors like the rise in the cost of oil and fertilizers.

In any case, biofuels are here to stay, with more and more sectors eager to invest in accelerating their development and commercialization so as to reduce their greenhouse gas emissions. The aviation industry is one such sector, with Virgin Atlantic making pioneering test flights back in 2008 using a mixture of palm oil and coconut oil. As a result, therefore, of the policy environment highlighted above, it is imperative that all the necessary steps be taken in order to ensure that biofuels are produced and consumed in an as sustainable manner as possible.

Bridge Design

Several factors must be considered before construction begins on any bridge. It is essential that engineers take into account not only the required length and width parameters to span the given gap but also the usage needs and anticipated volumes of the bridge, the costs and appropriateness of structural building materials, and the types and frequency of

relevant environmental conditions, such as earthquakes, tornadoes, or even annual periods of heavy rains. Taken together, all of these elements help define which of the main structural styles should be used to construct a bridge. The four principal bridge types are arch, beam, suspension, and truss. They can be used alone or in combination to create various bridge designs.

The main difference between the various bridge technologies centers on the length of a single span, which is the distance between two bridge abutments or supports that connect the bridge to the ground surface below. A single span of today's beam bridges, for example, can extend up to around 200 feet, while modern suspension bridges can extend 10 times that length or more, usually topping out at about 7,000 feet. Whichever underlying design is chosen, every bridge structure must take into account the forces of tension and compression, shear, torsion, resonance, and weather.

Types of Bridge Structure

The arch bridge is one of the oldest types of bridge design. It is founded on the principle of the Roman Arch, in which the two sides of a curved arch compress on each other at the peak, forcing tension to be pushed outward at the base. There it is controlled by supports at either end that brace the structure and make it stable enough to support a doorway, ceiling, or bridge. The ancient Romans built many arch bridges from stone and brick. Many of these 2,000-year-old structures still exist today, including the Pont du Gard aqueduct in France, which spans 300 yards at a peak height of 164 feet. The use of modern materials like steel and pressurized concrete enables contemporary arch bridges to be built with greater spans. While most arch bridges today extend to about 800 feet or less, one arch bridge in West Virginia, the New River Gorge Bridge, spans some 1,700 feet.

The beam bridge is another type of basic bridge construction that uses end supports to bear the load across its span. Beam bridges, however, use vertical or slightly angled piers to support horizontal beams that make up the deck of the bridge. The piers support the entire weight of the bridge and its traffic. The simple structure of beam bridges makes them a popular option to span short distances of approximately 250 feet or less. However, Louisiana's Lake Pontchartrain Causeway uses the beam

construction methodology to form a massive over-water bridge extending over 24 miles. To make the beam approach viable for such a great distance, engineers had to link thousands of individual beam-based spans to create the full bridge extension.

Longer bridges generally use suspension design or modern cable-stayed technologies to accommodate vast spans. Suspension bridges use two tall towers to suspend cables that support the bridge deck. The Golden Gate Bridge in San Francisco is a classic example. The towers of a suspension bridge support the bulk of the weight as compression forces push down on the deck, and then move back up the cables to the towers, dissipating the compression into the ground. The cables accommodate the tension forces on a suspension bridge by transferring the tension to the bridge anchorages that ground the bridge to the earth.

Cable-stayed bridges are a successor to traditional suspension bridges and are similar in appearance. However, they differ greatly in key design components. Specifically, cable-stayed bridges do not require anchorages or towers. Rather, their cables run from the roadway up to a single tower that shoulders all the weight and absorbs compression forces. The cables can be attached to the road in various ways, such as in a radial format, in which cables extend from multiple points on the road to a single point on the tower, or in a parallel pattern, in which the cables attach to the road and the tower at numerous points on both surfaces.

The truss bridge is a variation on the beam bridge design that features a load-bearing superstructure above, at, or below the bridge deck. It is composed of support beams connected in a triangular pattern. The use of a triangular pattern helps disperse the load burden across a wider area. Sometimes a truss formation is used to support cantilevered bridges by bracing above and/or below the bridge deck.

Structural Stressors

Tension occurs when two opposing sides of a bridge pull at each other, causing stress on the structural elements. Compression is when the structural elements press down on each other resulting in pressure stress on the structure. Each type of stress is capable of damaging the integrity of all or part of a bridge, especially as load weights and environmental factors come into play. Bridge engineers typically address these factors by choosing a design that

either dissipates the stress by spreading it out evenly over a broad area of the structure or by transferring it to stronger areas like the bridge supports.

Shear is a less likely threat to bridge safety but it does represent a viable concern for engineers. Shear stress on a bridge happens when two parts of the structure are forced in opposite directions. In a worst-case scenario, the forces of shear can rip bridge materials or the bridge itself in half.

Torsion represents another concern for bridge engineers constructing suspension bridges. Torsion occurs when high winds cause the suspended roadway to spin and bend in a motion similar to the waves of the ocean. Most of today's suspension bridges address the issue of torsion by adding a supportive aerodynamic truss system under the deck and using diagonal suspension cables to help reduce swaying and potential rippling of the roadway.

The issue of resonance involves vibrations and its effect on bridge integrity. It can begin as a comparatively minor event, such as wind battering a bridge. When the vibrations occur in relative harmony with the bridge's natural vibrations, it is not cause for alarm. If the vibration dramatically increases, however, it can send destructive vibrations resonating through the bridge structure in the form of harmful torsion waves. To reduce the effects of resonance, bridge designers typically incorporate dampeners designed to interrupt the resonant vibrations before they evolve into something more dangerous.

Weather is perhaps the greatest and most unpredictable threat to bridge construction. Natural forces such as wind, rain, snow, and ice pose ongoing concerns about bridge integrity and safety. Even some of the measures used to improve safe passage over bridges during inclement weather, such as spreading salt and sand on the roadways, can cause great damage to the structure of the bridge itself. Less frequent but more violent weather scenarios, such as hurricanes, earthquakes, and tornadoes, can destroy a bridge structure in seconds. While engineers cannot account for every scenario, they must consider potential hazards as part of their planning process.

Bridge Maintenance, Repair, and Replacement

Bridges are the most visible components of a transportation system. Maintaining, repairing, and replacing bridges involve critical investment decisions for agencies because of the high cost of these investments, the need to sustain an appropriate level of investment throughout the considerable life of a bridge, and the important structural and functional implications of the selected investments. Agencies, therefore, make the investment decisions to minimize life cycle cost and to provide safe and efficient mobility to transportation system users.

Most agencies use a computerized tool, a bridge management system (BMS), to manage and process relevant data and to provide analytical support for bridge program decisions. The BMS encompasses a system designed to optimize the use of available resources for the condition assessment, inspection, preventative maintenance, rehabilitation, and replacement of bridges.

Condition Assessment

Bridge structures are at risk from aging, leading to structural deterioration from severe environmental attack and service demands from increasing traffic and heavier loads, and from deferred maintenance. According to the U.S. Department of Transportation, 26.7 percent of the total bridges in the nation are either structurally deficient or functionally obsolete. The term *structurally deficient*

is used by the Federal Highway Administration (FHWA) to designate bridges eligible for federal funding. A structurally deficient bridge is one with routine maintenance concerns that do not pose a safety risk or one that is frequently flooded. To remain open to traffic, structurally deficient bridges are often posted with reduced weight limits that restrict the gross weight of vehicles using the bridges.

A structurally deficient bridge should not be confused with an unsafe bridge. A structurally deficient bridge, when open to traffic, typically requires significant maintenance and repair to remain in service and eventual rehabilitation or replacement to address deficiencies. To remain in service, structurally deficient bridges are often posted with weight limits to restrict the gross weight of vehicles to less than the maximum weight.

The term *functionally obsolete* is another FHWA term for classifying bridge eligibility for federal funding. A bridge is classified by the FHWA as functionally obsolete if it fails to meet its design criteria either by its deck geometry, its load-carrying capacity, its vertical or horizontal clearances, or the approach roadway alignment to the bridge.

Condition assessments of an existing bridge structure may be conducted to develop load rating, confirm an existing load rating, increase a load rating for future traffic, or determine whether the bridge should be posted in the interest of public safety. Changes in traffic patterns, concern about faulty building materials or construction methods, discovery of a design/construction error after the structure is in service, concern about deterioration discovered during routine inspection, and damage following extreme load events may prompt such evaluations. Posting or other restrictive actions may have a severe economic impact, which may depend on the trucking industry for distribution of resources and manufactured goods. The economics of upgrading or posting a bridge makes it imperative that condition assessment criteria and methods, either by analysis or by testing, be tied in a rational and quantitative fashion to public safety, function, and economics.

Condition assessment and safety verification of existing bridges, as well as decisions as to whether posting is required, are addressed through analysis, load testing, or a combination of methods. Bridge rating through structural analysis is by far

the most common and economical procedure for rating existing bridges. Load testing may be indicated when analysis produces an unsatisfactory result or when the analysis cannot be completed due to lack of design documentation, information, or the presence of deterioration. The customary rating process allows ratings to be determined through either the allowable stress method or the load factor method.

A third rating procedure found in the *Guide Manual for Condition Evaluation and Load and Resistance Factor Rating (LRFR) of Highway Bridges* is keyed to the new American Association of State Highway and Transportation Officials (AASHTO) Load and Resistance Factor Design (LRFD) method. The LRFR method is being introduced to the bridge maintenance community, and some states are beginning to use it in developing their bridge ratings. These rating methods may lead to different capacities and posted limits for the same bridge, a situation that cannot be justified from a professional engineering viewpoint and that carries serious implications with regard to the safety of the public and the economic well-being of businesses and individuals who may be affected by bridge postings or closures.

Inspection and Preventative Maintenance

The National Bridge Inspection Standards (NBIS), which were implemented in the 1970s, established a single, unified method of collecting data on the nation's public highway bridges. In the United States, these data are submitted annually by state Departments of Transportation (DOTs) to the FHWA, which compiles them within the National Bridge Inventory database. The NBIS have enabled the FHWA and state DOTs to monitor bridge condition and performance nationally on a consistent basis, identify bridge needs, define criteria of project eligibility for federal bridge funding, and thereby promote public safety through better stewardship of bridge assets.

Preventative bridge maintenance is defined as a planned strategy of cost-effective treatments applied at the proper time to preserve and extend the useful life of a bridge. Transportation Asset Management is driven by policy and performance and considers alternatives and trade-offs, evaluating competing projects and services based on cost-effectiveness and anticipated impact on system performance. As such it employs systematic, consistent

business processes and decision criteria and makes good use of information and analytic procedures.

In order to maintain and repair bridges within limited budgets in the United States, DOTs are establishing procedures for early detection of problems, timely repair, good preventative maintenance routines, and consideration of long-term effectiveness of dollars spent. The AASHTO bridge management software, Pontis, can be used to inventory elements of a bridge, run deterioration and cost models to determine long-term preservation policies, determine preservation needs and schedules, and provide network-level performance measures.

European models have gone further in incorporating environmental aspects. The LIFECON Life-Cycle Management System (LMS) is a European model of a predictive and integrated LMS for concrete infrastructures, on both a short-term and a long-term basis, developed to facilitate decision making. The system is divided into three levels of structural hierarchy: component and module, object, and network, with component- and module-level systems that address structural components such as beams and columns and their combinations in modules.

The object-level system deals with complete structures or buildings. The network-level system treats networks of objects such as stocks of bridges or buildings. Besides bridge structure condition and urgency of repair, the life cycle costs, user costs, minimum requirements of structural performance, structural risks, traffic and other operational requirements, aesthetics, environmental risks, and ecological pressures can be taken into account for multiple-attribute planning on all hierarchical levels of the system.

The life cycle analysis and optimization module involves the data applications for studying the economy of the life cycle and cost-effectiveness of optional maintenance, repair, and rehabilitation strategies. Alternative strategies are compared as life cycle activity profiles over a defined time frame. The purpose of life cycle analyses is to find the optimal activity profiles to reach the targets.

In January 2002, FHWA announced that Highway Bridge Replacement and Rehabilitation Program (HBRRP) funds can be used to perform preventive maintenance on highway bridges. Preventive maintenance activities eligible for funding include sealing or replacing leaking joints,

applying deck overlays that will significantly increase the service life of the deck, painting the structural steel, and applying electrochemical chloride extraction treatments to decks and substructure elements. FHWA is currently in the process of clarifying language and restructuring the NBIS. Proposed changes will reorganize the standards into a more logical sequence and make them easier to understand for inspectors and state and federal highway administrators.

Replacement or Rehabilitation

Decisions for replacement or rehabilitation are based on many factors, including the structural condition, the benefit of extending the remaining service life of the structure resulting from repairing the deficient structural components, the repair cost, and the traffic disruption associated with lane closures, among others. The choice of the retrofitting technique is based on the condition severity of the deficient structural components. Retrofitting techniques range from strengthening deficient components to replacing the whole structure. Common retrofitting or strengthening techniques include the use of steel jackets, fiber-reinforced polymers (FRP) and composites, bridge deck overlays, external prestressing, and shotcrete application.

Bridges, Condition of

The American Society of Civil Engineers gave the nation's bridges a C+ in its 2013 report on America's infrastructure, up a fraction from the C that bridges received in the 2009 report. Yet with one in nine of the 607,380 bridges in the United States rated as structurally deficient and a shortfall of nearly \$8 billion annually in meeting the estimate given by the Federal Highway Administration (FHWA) for eliminating the deficient backlog by 2028, progress is at best modest.

Meanwhile, each day Americans take 200 million trips across deficient bridges in the 102 largest metropolitan regions. According to the lobbyist group Transportation for America, nearly a third of the country's bridges are more than 50 years old. By 2030, over half of existing bridges will be at the end of their design life.

Forty states decreased the percentage of deficient bridges from 1989 to 2008. Nationally, the number fell from 37.8 percent of all bridges in 1989 to 23.7 percent in 2008. But in 2008 all states combined spent \$8 billion, or a mere 13 percent of federal transportation funds, on repair and rehabilitation of bridges. Federal estimates to eliminate the backlog of needed repairs for 2008 was \$61.4 billion. Despite the billions spent, the number of vehicles traveling

across bridges classified as structurally deficient declined only 2 percent between 1992 and 2010.

National Bridge Inspection Standards

The National Bridge Inspection Standards were developed as a result of the Federal Aid Highway Act of 1968. The standards went into effect for all public bridges on federal highways in 1972, and thereafter routine inspections were mandated at least once every two years. In 1978, the inventory was extended to include all public bridges greater than 20 feet. The standards were adopted by all state transportation departments.

Inspectors categorize bridges that rank as less than 5 on a 9-point scale as structurally deficient, functionally obsolete, or fracture critical. The deck (riding surface), the superstructure (main supporting element of the deck, usually beams, girders, trusses, etc.), and the substructure (supports to hold up the superstructure and deck, usually abutments and piers) are rated on a scale from zero (closed to traffic) to 9 (excellent condition). A bridge receives a structurally deficient rating if any one of its main elements is rated 4 (meets minimum tolerable limits to be left in place as is) or less. States are quick to assure the public that structurally deficient bridges are not unsafe. The label *structurally deficient* is intended to sound an early warning that making repairs or building a replacement should become a priority. Speed or weight restrictions may be placed on the functionally deficient bridge.

Functionally obsolete bridges are those built to earlier standards that fail to meet current minimum federal requirements. These bridges are not automatically rated as structurally deficient, nor are they inherently unsafe. Functionally obsolete bridges include those that have substandard features, such as narrow lanes, narrow shoulders, poor approach alignment, or inadequate vertical under clearance. The Chesapeake Bay Bridge in Annapolis, Maryland, built in 1951, received one 5 (fair) and two 6s (satisfactory) in its 2011 inspection, but it is considered functionally obsolete.

A fracture critical bridge lacks redundancy. It typically has a steel superstructure with load (tension)-carrying members arranged in such a manner that if one fails, the bridge could collapse. The classification of “fracture critical” does not mean the bridge is inherently unsafe. About 18,000 bridges across the country have been deemed

fracture critical. The most famous fracture critical bridge is the I-35W Mississippi River Bridge, an eight-lane bridge in Minneapolis, Minnesota, that collapsed during the evening rush hour on August 1, 2007, killing 13 and injuring 145.

About 140,000 cars and trucks crossed that 40-year-old bridge daily, the same number that cross the 57-year-old, seven-lane Tappan Zee Bridge that connects the northern suburban counties of New York City. A new \$3.1 billion replacement bridge is scheduled to open April 3, 2018. The Pulaski Skyway between Newark and Jersey City, which was built in 1932, is scheduled for a \$1 billion rehabilitation beginning in 2014.

Workload for the States

Although states depend upon federal funds channeled through the Highway Trust Fund for a substantial portion of monies used to maintain and repair bridges, the greater portion of funds must come from state and local budgets. State governments finance these projects through taxes and fees that vary from state to state. Just as the federal motor fuel excise tax of 18.4 cents per gallon of gasoline (unchanged since 1993) provides the major source of funding for federal investment in the maintenance and repair of the nation's bridges, gasoline taxes levied by the state provide the major source of funding at the state level. State gasoline tax rates range from a low of 8 cents per gallon in Alaska and Georgia to a high of 38.16 cents in California, with an average of 23.47 cents per gallon.

Pennsylvania has the most deteriorating bridges. Of the state's 25,000 bridges, 26.5 percent are deficient. For fiscal year 2012–13, Pennsylvania invested a total of \$4.4 billion in its highways and bridges: \$2.8 billion (64 percent) in state funds and \$1.6 billion in federal funds. As of June 2012, the state had 4,774 deficient bridges, the lowest since before 1998. Another 600 bridges should be repaired by 2014. Federal stimulus dollars provided through the American Recovery and Reinvestment Act enabled Pennsylvania to improve at this rate, but to reach the national average of 11.5 percent, the state must repair 400 bridges each year through 2033. But the federal stimulus package has ended, and the state has a budget deficit.

Pennsylvania's bridge problems may be the most severe, but the state's problems are not unique. Twenty-two other states have a higher percentage

of deficient bridges than the national average of 11.5 percent. The five states with the worst bridge conditions all exceed a 20 percent share of structurally deficient bridges. With Americans driving more fuel-efficient cars and buying less gas because of higher gas prices, state revenue from fuel taxes is likely to continue to decline. At the same time revenue is declining, costs of labor and such essential materials as steel, asphalt, and concrete have all risen by at least 50 percent.

A Bleak Future

A boom in bridge building coincided with the baby boom in the United States from the mid-1950s to the mid-1970s. These bridges are all aging, and many of them are already reaching the end of their design life, an estimated 50 years. Many bridges support a greater traffic load than their designers imagined. According to the American Association of State Highway and Transportation Officials

(AASHTO), American bridges bear more than 3 trillion vehicle miles (4.8 trillion vehicle kilometers) of travel each year, and trucks contribute 223 billion vehicle miles (359 billion vehicle kilometers) of that total. When states are unable to meet the need for bridge maintenance, their only choice is to limit loads and close bridges. These actions increase traffic on other bridges, which increases the rate at which they will need repairs and multiplies traffic congestion, particularly in urban areas.

An AASHTO report released in 2008, representing state departments of transportation, concluded that federal, state, and local governments will have to increase transportation investment to preserve resources and meet future needs. Central to the AASHTO plan is implementation of systematic, long-term maintenance programs for existing bridge infrastructure. The group also sees as essential the consideration of a variety of financial options, including tolls, taxes, user fees, and bonds, as well as

Partially submerged cars in the Mississippi River beside the remnants of the collapsed I-35W bridge in Minneapolis, Minnesota, on August 5, 2007. The collapse of the fracture-critical steel truss arch bridge four days earlier during the evening rush hour killed 13 people. In 2013, one in nine of the 607,380 bridges in the United States were found to be structurally deficient, resulting in American drivers making a total of 200 million trips per day across deficient bridges in the 102 largest metropolitan regions.

other forms of private investment. Increased public awareness and a strong commitment to research and innovation are also essential.

Bureau of Budget Circular A-95

Federalism has been a central political issue throughout the history of the United States, beginning with the replacement of the Articles of Confederation by the Constitution. The balancing of federal–state and state–local governmental authority and responsibility has continued to coevolve with changes in our population, economy, and political parties. The first half of the 20th century, which included two world wars and the Great Depression, saw the steady growth of the federal government. Political scientists have called federalism during this period "cooperative." The creation of the Federal Aid Road Act of 1916 is a prime example. All subsequent federal transportation-related legislation and programs have necessarily addressed the centralization–decentralization aspects of funding and decision making. The U.S. Bureau of Budget's Circular A-95 played a central role in framing the

federalism aspects of transportation planning and program implementation during the transformative decade of the 1970s. Collaborative decision-making lessons from this experiment continue to inform transportation policy today.

Post World War II, Congress embarked on an ambitious set of initiatives to generate a reinvigorated peacetime economy. Included were the Interstate Highway System, and urban renewal. The former sent federal aid to rural-oriented state highway departments that were charged with locating, constructing, and operating an entirely new class of major facilities throughout their state, including dense urban centers and their rapidly changing suburbs. In contrast, urban renewal sent federal funds directly to single-purpose, nonelected local agencies that had been created specifically to administer this program of acquiring and clearing large structurally deficient areas for transfer to private developers. Infrastructure and land use are tightly coupled systems. For half a century, states had delegated plan-based land use control to its individual local governments. In contrast, these and other new federal programs generated regional zones of change and conflict that transcended municipal boundaries.

The Dwight Eisenhower administration was deeply concerned about the scope and direction of these unintended programmatic effects and worked with Congress to create in 1959 the Advisory Commission on Intergovernmental Relations (ACIR). It was a "permanent organization" with members appointed from Congress, the executive branch, governors, state legislatures, counties, cities, and citizens that worked with a small professional staff to analyze and recommend new directions in federalism.

The 1960s was a volatile decade. Cities were being bulldozed, race riots broke out, and suburban sprawl accelerated, all within the broader context of the Vietnam War controversy over misuse of federal power. Of particular concern to publics and policy makers were metropolitan areas. In previous decades, the decennial U.S. Census of Population and Housing had differentiated between "rural" and "urban" areas to provide guidance to congressional programs. By 1950, "urban areas" were defined as having a population over 50,000. The 1960 census included new statistical sample questions on location of work and mode of transportation. These

were used to designate Standard Metropolitan Statistical Areas (SMSAs), which consisted of central urban areas and adjacent, trip-to-work related counties. This census revealed that two-thirds of the nation now lived and worked in metropolitan areas.

Three laws from this period built directly upon the ACIR's initial reports. Together these laws represent the move toward "creative federalism." The 1962 Federal Aid Highway Act included the "3-C" requirement of continuing, comprehensive, cooperative planning in all census-designated urban areas. "Comprehensive" included existing and future land use, which was basis for the new traffic modeling approaches. "Cooperative" meant the involvement of federal, state, and local agencies and elected officials.

Congress passed the Demonstration Cities and Metropolitan Development Act in 1966, commonly known as "Model Cities." Its findings included recognition that the complexity and fragmentation of local governments and special districts in rapidly growing metropolitan areas was hindering the effective use of federal-aid programs. It mandated that all local and state applications for grants and loans for transportation facilities, airports, water and sewer, and other development projects within a metropolitan area, were to be reviewed for consistency with area-wide development plan and policies by a regional planning agency composed of an area-wide government (such as a Council of Government), or a Regional Planning Board composed of elected local governments. This was an explicit top-down mandate by the federal government to the states about how they were to internally organize themselves in metropolitan areas. Although it could not be enforced constitutionally, no state had an interest in cutting off federal programmatic aid. At the federal level, "Model Cities" was an attempt to reinvent the Department of Housing and Urban Development's (HUD) problematic Urban Renewal Program. The HUD administrator was designated to coordinate metropolitan development programs within the federal agencies.

To implement this law the Bureau of Budget (now the Office of Management and Budget) issued Circular A-82. A small but important grassroots movement toward metropolitan facility management was already under way in some states that had created regional planning commissions (RPCs) or

Councils of Government (COGs) to address specific emergent metropolitan issues, such as water supply, commuter rail financing, and jetport siting. The Twin Cities of Minneapolis and St. Paul, Minnesota, have often been used as a model from this period. These organizations were funded in part through the 1954 Housing Act, which identified area-wide planning in metropolitan regions as an important complement to municipal planning.

A-82 encompassed 32 physical development-related programs that had to be reviewed for consistency with an area-wide development plan. Where they already existed, states typically designated RPCs and COGs for the clearinghouse function. Some of the latter, such as the Denver Regional Council of Governments, were also responsible for 3-C transportation planning. Where no RPCs existed, they were created. Some RPCs evolved into COGs in order to meet the law's "composed of elected officials" requirement.

Circular A-95

Implementation of A-82 was just starting up when Congress passed the Intergovernmental Cooperation Act of 1968. This was a comprehensive piece of fiscal management legislation aimed at providing governors with better information for planning and managing the increasing role of all federal aid programs within their states and for improving interagency coordination between the federal departments. To implement this law, the Bureau of Budget issued Circular A-95 in 1969, which superseded A-82. Added to A-82's metropolitan regional clearing house function was the requirement for regional clearinghouses to review programmatic grant programs in all nonmetropolitan areas.

In addition, a new tier of state clearinghouses was required to receive all grant requests made by their agencies and units of local government. Over the next decade, the Bureau of Budget expanded the number and scope of programs required to undergo review. Starting with 51 programs, A-95 was increased to 100 programs in 1971 primarily with the addition of new health, job, and social services congressional initiatives. By early 1980 it had reached 259 programs.

Functionally, A-95 was designed as an "early warning" information system between five sets of institutional actors: the White House Bureau of Budget, regional clearinghouses, state clearinghouses,

local and state government applicants for federal programmatic grants, and the federal agencies administering grants. Information flow was structured by the Project Notification and Review System (PNRS).

Applicants for designated grant programs sent a notice of intent (NOI) including location information and a summary description to the state and regional clearinghouses. Clearinghouses had 30 days to determine whether there might be conflicts with state or area-wide policies and plans. This often involved forwarding the NOI to appropriate local governments and agencies. If no issues were identified, the applicant was cleared to submit their federal grant application. If potential issues were identified and not resolved, the applicant was required to submit the entire application for detailed review and comment to the clearinghouses. Within 30 days, the application and clearinghouse comments were sent to the federal grant agency. Granting agencies then processed the applications, including consideration of comments. Applicants and clearinghouses were notified of the decisions.

In his 1981 inaugural address President Ronald Reagan stated: "The federal government did not create the states; the states created the federal government." In 1982 he issued Executive Order 12372, Intergovernmental Review of Federal Programs. This executive order was part of his larger administrative reform initiative "devolution," the reduction of federal authority by transfer to the states. It revoked A-95, eliminating the mandate for state and regional review as a requirement for federal grants. It encouraged states to establish their own approaches for coordinating local-regional-state-wide interests. Over the next few years, many of the programs that had been included under A-95 were either eliminated or consolidated into "block grants" that gave state and local governments considerable expenditure flexibility. Today, the Federal Office of Management and Budget maintains a list of "official state agencies" designated by governors, the Single Point of Contact (SPOC). Federal program granting agencies are required to coordinate with these state units in grant application processing. Less than half the states currently participate in SPOC.

Controversies and Critiques

From a transportation perspective, the A-95 program was controversial throughout its decade-long

existence. Issues may be grouped into four categories: institutional capacity, federal agency "buy-in," obsolescence, and substate complexity. Capacity encompasses the professional staff, budgets, and information resources of the regional clearinghouses and the orientation to A-95 from the clearinghouse leadership. The short-lived A-82 metropolitan-based clearinghouses were conceptually a good fit with the prevailing administrative approach of applying rational planning to the disjointed physical development programs and jurisdictions to be reviewed. However, unlike municipal planning, which had evolved over a half century that was tightly coupled to elected legislatures and program implementation, there were no standards or guidelines for metropolitan plans. 3C transportation planners often had to work with a patchwork of conflicting existing municipal plans and their more generalized regional growth trend forecasts. For many of the clearinghouses, their regional development plans were in process, neither completed nor adopted, and the plans tended to be quite general. This raised serious questions regarding the basis for plan conformity review.

A particularly volatile topic of concern involved state highway departments implementing the Interstate Highway program in metropolitan areas. Prior to A-95, the Bureau of Public Roads interpreted the 3C "cooperative" requirement as allowing states to negotiate agreements directly with local officials, thereby bypassing the regional planning organizations. The A-95 process posed a potential "veto" by a regional council. Although A-95 called for a single metropolitan clearinghouse, the large range of programs involved, from sewers to transit to civil rights to crime, was a poor fit with both the interests and the technical capacity of transportation-focused planning organizations.

The 1970s are known as the "environmental decade" for sweeping new federal legislation, starting with the National Environmental Policy Act of 1970 (NEPA). Initially, this law's mandate for environmental impact analyses was highly contested in the courts, but by the time of the issuance of the NEPA regulations in 1978 the Supreme Court had upheld its procedural mandate for all federal agencies. The NEPA regulations specified a comprehensive multidisciplinary, federal-state, local, and public collaborative analysis and review process for all federally aided transportation projects. The 1973 Federal Aid

Highway Act created Metropolitan Planning Organizations (MPOs) funded from the Highway Trust Fund. MPOs were required to have representation by local elected officials as well as transportation-related agencies. The OMB subsequently revised A-95 to allow the MPOs to provide the A-95 review for transportation projects. NEPA coupled with the MPOs had essentially rendered A-95 obsolete.

The A-95 process was also critiqued from the perspective of wasteful, ineffective paperwork. There were no substantive analyses of the program's functionality or cost-effectiveness. Clearinghouses faced a fundamental challenge of operating a distributed information and analysis mandate within 30-day time limits in the predigital era. There was no word processing, Internet, or geographical information systems (GIS). Anecdotal evidence consistently reflected that the reviews and comments were necessarily superficial. The OMB had required the creation of clearinghouses and the review of grants for consistency with plans, but it did not require functional plans. States were generally ambivalent on this issue. There was no federal or independent analysis of whether A-95 had any influence on the grants. In many regions, the prime operational objective of the clearinghouse was to maximize the flow of federal aid.

In this period, the federal government was not able to assess an administrative program such as A-95. Both the Bureau of the Budget and the General Accounting Office (GAO) were primarily focused on tracking monetary flows for waste or misuse. Today the OMB and the General Accountability Office are deeply involved in assessing the outcomes effectiveness of federal programs. This is done in collaboration with the agencies. All DOT programs are analyzed with OMB as part of the continuing federal budget process. The GAO undertakes specific analyses at the request of a member of Congress concerned about the performance of a particular program. Their reports are public information.

Conclusion

Congressional funding for the ACIR was eliminated in 1996 after a decade of slow decline in both studies and influence. The A-95 approach has been interpreted by some as a shallow bureaucratic one-size-fits-all example of how not to handle the rich diversity of regions within the United States. Others, particularly from the perspective of rural areas,

have seen it as a flawed but necessary transitional approach in a period of rapid change that supplied impetus for regional collaboration. The underlying dynamics of federalism, particularly for metropolitan transportation systems, is today an active arena of innovation and experimentation. The evolution of multimodal transportation funding legislation; the increased roles of MPOs, including project programming, public participation, and Clean Air Act coordination; and "smart growth" demonstration initiatives partnering with the EPA are all consistent with the historically important role of states and localities as the "laboratories of democracy."

Bureau of Public Roads

At the end of the 19th century, traffic on most American roads consisted of wagons, coaches, horses, bicycles, and pedestrians. However, the national government was beginning to recognize the need for federal involvement in building and maintaining roads and ensuring the safety of Americans who traveled those roads. In 1893, the

first national highway agency was established as the Office of Road Inquiry (ORI). The first head of ORI was General Roy Stone (1836–1905), an engineer and former officer in the Union army who was a strong believer in the need for improving public roads in the United States. His first annual budget was \$10,000. The name of the agency was changed to the Office of Public Roads in 1905 when it became part of the Department of Agriculture. In 1915 a third name change designated the agency as the Bureau of Public Roads.

Yet another name change occurred during the New Deal, and in 1939, the agency became the Public Roads Administration, operating under the auspices of the Federal Works Agency. By that time, the focus was shifting away from rural areas and toward urban areas where most transportation problems were surfacing. Officials at national, state, and local levels had all become concerned with traffic congestion, urban decay, and the loss of tax monies as Americans moved away from large cities.

When the Federal Works Agency was dismantled in 1949, the Public Works Administration reverted back to being the Bureau of Public Roads under Reorganized Plan No. 7 and became part of the Department of Commerce. When the Department of Transportation (USDOT) was established in 1966, the Bureau of Public Roads was folded into the USDOT, and its responsibilities were subsequently transferred to the newly established Federal Highway Administration (FHWA).

Early History

In 1905, the Division of Tests, which was part of the Bureau of Chemistry, was combined with the Office of Public Roads (OPR) in the Department of Agriculture. The combined agency retained the name Office of Public Roads. That same year, the U.S. Forest Service was created, and OPR immediately began providing professional services to the new agency. The OPR also continued to advise other federal agencies engaged in any aspect of road construction. In 1912, Congress passed the Agricultural Appropriations Act, which provided funds for constructing new roads and trails and improving those already existing on public lands. Another provision of the act appropriated funding for improving roads designated as “Postal Roads.” State and local governments were required to assist in the latter endeavor by providing matching funds. The

following year, Congress appropriated new funds to continue the project.

In 1916, Congress passed the Federal Aid Road Act, which established the Federal Aid Highway Program, officially recognizing the commitment of the national government to expanding the highway system within the United States. This meant that the federal government needed a professional corps of engineers within the Office of Public Roads to oversee the program. The following year, 10 district offices were established and charged with working with state and local governments to construct Post Roads. These regional offices also continued to work in partnership with the National Forest Service and state and local governments on surveying, constructing, and maintaining roads located within national forests. The Agriculture Appropriations act of 1919 renamed what had come to be called the Office of Public Roads and Rural Engineering, and the agency became the Bureau of Public Roads (BPR).

Expanding Responsibilities

In the 1920s, both Ford and General Motors were manufacturing cars that were taking to American highways. Under the leadership of Henry Ford (1863–1947), the Model T was the first choice for many families until Ford introduced the Model A in 1927. General Motors, on the other hand, provided greater choice, offering different models for different markets. GM manager Alfred P. Sloan, Jr., (1875–1966) was the first to conceive the benefits of a used-car market that allowed owners to trade in old cars and use the proceeds to buy more expensive vehicles. By the end of the decade, the American highway system had grown to 830,000 miles of paved roads, and the number of automobiles had climbed to 23 million.

In order to meet the needs of the expanding transportation sector, the national government was willing to commit considerable resources. Those resources consisted of providing financial assistance and technical knowledge, and sharing information. As the national agency charged with responsibility for overseeing highways, the Bureau of Public Roads was poised to play a major role in the development of the contemporary United States.

In 1921, Congress passed the Federal Highway Act, reauthorizing the existing highway program. The 1921 act was also designed to provide support

A 1990 view of the “Weeping Wall” roadside waterfalls on Going-to-the-Sun Road in Glacier National Park in Flathead County, Montana. The 51-mile scenic road was partly carved out of a mountainside. It was the first project to follow a 1925 Memorandum of Agreement for collaboration between the National Park Service and the Bureau of Public Roads.

to encourage transcontinental highway travel, encourage state and local communities to develop their own resources, and promote conservation and the development of national resources. Regional offices established under the act took on responsibilities for coordinating efforts within designated areas. The act also established a tax on motor fuels to be used to fund the activities of the Bureau of Public Roads, which had been assigned responsibility for constructing a national system of paved two-lane highways.

In 1924, Congress authorized major road construction within national parks, and the Bureau of Public Roads signed a Memorandum of Agreement pledging to work with the National Park Service on the project. By 1926, Route 66, a major national highway connecting Chicago with Los Angeles, had been completed. To simplify matters, BPR designated roads running north to south with odd

numbers. Roads traveling from east to west were assigned even numbers. By the time the 1920s drew to a close, some \$200 million had been spent on American highways each year of the decade.

Some of the early projects conducted by the Bureau of Public Roads still stand as permanent testaments to the agency's contributions to developing American highways. In 1928, the BPR was assigned responsibility for locating, designing, and building the Mount Vernon Memorial Parkway. The completion date was set for 1932 in order to celebrate the 200th anniversary of the birth of George Washington, the nation's first president. The parkway ran along the Potomac River and was designed to maintain the beauty of the area by following the contours of the land. In the 21st century, that parkway is part of the George Washington Memorial Parkway, and it is still considered one of the Bureau of Public Roads' major accomplishments. Other

BPR contributions can be found in national parks located throughout the United States, including Grand Canyon, Mount Rainier, Rocky Mountain, Sequoia, Yellowstone, Zion, Great Smoky Mountain, Shenandoah, and Everglades.

The work of the Bureau of Public Roads also extended into U.S. territories. For instance, in 1933 the BPR began working with the National Park Service and local officials to design and build Hawaii's Haleakala Highway. Local officials depended heavily on the technological knowledge of the BPR's engineers to design and construct the road without destroying the natural environment of Haleakala National Park, which connects the islands of Hawaii and Maui. The park was established on a dormant crater and was one of the most isolated spots in the world at the time. After the highway was completed in 1935, it began drawing large numbers of tourists to the islands.

Shifting Priorities

During the early years of the Great Depression, which continued throughout the 1930s, the BPR was heavily involved in working with state and local governments to put Americans to work building roads under the New Deal's public works projects. In 1939, a Bureau of Public Roads report titled *Toll Roads and Free Roads* clarified the shift in focus to urban roads as the nation's attention turned to the issue of building a national highway system that would connect the country from coast to coast and from border to border. When the Bureau of Public Roads became the Public Roads Administration on July 1, 1939, under President Franklin D. Roosevelt, it continued to fulfill its ongoing responsibilities.

According to American legend, it was FDR who first articulated the notion of connecting the United States via a system of interstate highways. The legend credits Roosevelt with drawing three lines stretching north to west and another three lines traveling from north to south on a map and instructing the Bureau of Public Roads to turn those lines into six interstate highways. The validity of the legend is in doubt, according to highway historian Lee Mertz, but it is true that in Section 13 of the Federal Highway Act of 1938, Congress requested the head of the BPR to investigate the feasibility of building an interstate highway system.

Newspaper reports of the day also recorded Roosevelt's interest in building an interstate system.

The *Washington Post* suggested that he intended to fund the new highway program through a \$4.88 billion works program. Two years earlier, Roosevelt had expressed support for a proposed congressional bill designed to construct 10 transcontinental highways to serve as both a national defense mechanism and an economic stimulator.

After the agency became the Public Roads Administration (PRA) in 1939, its work as part of the Federal Works Agency involved working closely with the Department of the Interior and the U.S. Postal Service, providing advice on locations and furnishing technical expertise on road design and construction.

After the Japanese attacked Pearl Harbor on the morning of December 7, 1941, the United States was plunged into World War II. All existing projects were placed on hold as the PRA turned to assisting the military with defense projects. American highways came into heavy use during the war years because of the toll exacted by transporting troops and heavy military equipment. By the time the war ended in 1945, most American roads were in serious need of repair.

In 1944, Congress passed the Federal Aid Highway Act, which authorized the building of 40,000 miles of national highways. The Bureau of Public Roads was assigned a major role in the project, including responsibility for dispersing some \$125 million in funding. Those funds were not sufficient for completion of the project. Building a national highway system proved extremely costly for the poorest Americans, who were predominantly African American and immigrant. Those populations often witnessed the destruction of their homes as land was cleared for the national highway project.

Dreams to Reality

In 1949, the Public Roads Administration became part of the new General Services Administration and reverted to the name Bureau of Public Roads, working under the Department of Commerce. In 1956, the Federal Aid Highway Act called for reorganization within the BPR. The Federal Domain Division, which subsequently became the Federal Highway Projects Division, was charged with overseeing the construction of national highways. The postwar years were characterized by economic prosperity in the United States, and President Dwight D. Eisenhower was finally successful in convincing Congress to pass the Federal Aid

Highway Act of 1956, which provided sufficient funding for building the interstate highway system that FDR had envisioned.

The functions of the Bureau of Public Roads continued to evolve over time. By the 1960s, mass transportation was becoming increasingly important because of traffic congestion in large cities and concern over the environmental damage caused by burning fossil fuels. In 1966, the Department of Transportation Act established the Department of Transportation. On April 1, 1967, the Bureau of Public Roads was transferred to the DOT, and its responsibilities were assigned to the Federal Highway Administration (FHWA).

Bus Capacity

Bus capacity is the total number of passengers a public transit bus may safely carry. This number is quantified by a factor known as the load ratio. This ratio is the total number of travelers a bus may facilitate, including seated and standing passengers. If a bus goes above this load ratio, it is considered overcrowded. However, just because individual buses or lines are overcrowded does not mean that the total system is running above, or even at, capacity. Even in cities with perpetually overcrowded lines, there are likely many lines that frequently run far under capacity. In fact, it is possible for a city bus line to run at under 50 percent capacity while certain lines are constantly overcrowded. Overcrowding on buses can cause problems, including passenger discomfort, difficult bus entries and exits, and exacerbation of delays. There are several issues that may cause this condition, including improper staffing, not enough buses, lack of funding, improper distribution of resources, or ineffective line placement. If these issues were resolved, it is possible that many overcrowding problems would be resolved.

Interpreting Load Ratios

The industry standard maximum load ratio is 1.25. If all seats are filled but there are no standees, the ratio is said to be at 1.00. If all seats are full and a number of people equal to 25 percent of the total seats are in standing positions, the bus is said to be at a ratio of 1.25. Thus, if a bus with 40 seats, has 50 people on it, the ratio is 1.25, the maximum available ratio.

The maximum allowable ratio is not a hard and fast rule. Depending on the situation, the maximum

ratio may go up or down. On highways or express lines, where the bus is expected to travel at a faster rate of speed, ratios are often kept at or around 1.00. This is because it is widely thought that these buses travel too fast to facilitate a significant number of standees. The load factor on a given line may also shift based on the time of day. This is done to facilitate a greater demand and keep wait times at bus stops tolerable.

Adjustment of the Maximum Ratio

While it may have been reasonable in previous eras, there is debate over whether the load ratio of 1.25 is still appropriate for today's modern buses. Since the present load ratio was established, the industry has transitioned from high-floor buses to low-floor models. Low-floor buses have been adopted by bus services nationwide due to their increased handicapped accessibility. Low-floor buses are designed with a minimal number of steps between one or more entrances and part or all of the passenger cabin. With this major adjustment, the design improves accessibility to handicapped, elderly, and otherwise infirm individuals. Low-floor buses are also capable of hydraulic lowering and other features that enable an improved experience for wheelchair users.

The load factor of 1.25 was adopted as an industry standard during a time when the standard bus had a high floor. Such high-floor buses were typically 40 feet long and had 47 seats. Today's buses are significantly lower than the previous high buses. The standard 40-foot low bus has 38 seats. Thus, to carry the same number of passengers as high buses, low buses must carry a greater number of standees. Additionally, standard low-floor buses require standing passengers to stand closer together by eliminating stair well and wheel standing spaces and adding wheelchair access spots. Considering the space constraints placed on standees on low-floor buses, industry experts have proposed that the load ratio be lowered to 1.20 for low-floor buses.

Solving Overcrowding

There are several potential methods that could be used to alleviate overcrowding on metropolitan buses. Many of these methods could stand on their own, but others are dependent on each other to see their full effect. At the most basic level, cities that face critical overcrowding need to either add

more buses to their fleets or review their existing lines. It could be that the lines within the city are inefficiently distributed; thus, if lines are put where they can be more effective, load factors would lower while total system capacity would rise. If lines are already at their most efficient, bus systems must purchase additional buses. Once fleets are expanded, the frequency of schedules may be increased, thus lowering capacity.

Additionally, if systems are able to invest in better buses, they could purchase models with greater capacity, those with prepay toll systems that would free up standing room in the front of the bus, or articulated buses that allow for additional standing room. Finally, if a fleet has enough vehicles to spare, it can create express routes or Bus Rapid Transit that can quickly and effectively transport passengers from high-traffic area to high-traffic area, thus alleviating load ratios in the rest of the system.

Bus Design

A bus is an autonomous road vehicle designed to carry passengers and their personal effects. A bus driver steers the vehicle and determines the safe speed of operation on a particular road. A bus usually carries enough fuel or energy to be able to operate at least from one end of its route to the other without refueling. The exception to this is trolleybuses, which are powered from overhead electric cables.

Present-day motor buses have been developed progressively from horse-drawn omnibuses of the 19th century. This development includes motive power, wheels, suspension, speed, size, passenger comfort, and capacity. Operational developments have included the switch from two-man to one-person crews, and passengers buying tickets prior to making the bus journey.

During this time the motor car has been developed even more rapidly, and where once buses catered to a carless “captive” population, today in many countries most people have cars, which is their prime mode of travel. Buses are now used mostly by people without a car, or who cannot drive. In many countries various classes of people are issued free bus passes, for example, pensioners, disabled, and school children, who make up the majority of passengers.

Development

In 2012 some 193,000 buses were manufactured worldwide, with the top five countries (China, Brazil, South Korea, Russia, and Japan) producing 78 percent of them. In comparison, 21 million trucks were built worldwide. The importance of this is that bus production is not large enough in any country to support mass production as a single product vehicle. Bus costs are kept relatively low by using mass-produced parts from the truck industry, including engines, gearboxes, axles, suspension, and steering.

The motor bus development was accelerated by World War I, when lorries were used to carry supplies to war zones and buses carried soldiers. At the end of that war, many surplus buses and trucks were put into service for both urban and rural traffic. This first generation of buses was powered by gasoline engines and ran on solid-rubber tires. With the poor state of road surfaces, this gave a most uncomfortable ride compared to streetcars, that dominated urban transit at the time. Two

developments improved ride quality: first, tarmac (smooth) surfacing of roads, and second, the adoption of pneumatic tires.

World War II brought diesel engine reliability to the same level as gasoline engines with better fuel economy; this led to the rapid replacement of gasoline engines with diesel engines for buses.

Technology

The technology used for buses piggybacks on the mass truck market. In the last 30 years there has been a rapid change in the way buses are designed and operated. Historically, the bus engine and steering wheels were at the very front of the bus, with the entrance at the back or in the middle. This required a two-man crew—a driver and a conductor who collected the fares. Due to limitations of tires, these buses were small, carrying about 40 passengers, and in a number of countries also included an open-top upper deck, allowing about 50 passengers. These first buses weighed only about four tons.

As tire technology improved, buses got progressively longer, wider, and heavier. The economics of operation, especially in cities where fares are set politically, led to the adoption of one-man operation, requiring the driver to collect fares or check tickets. This led to both the steering wheels (forward control) and the engine being moved away from the front of the bus. Various alternative engine positions were tried—vertical mid on one side, horizontal under the floor, and vertical across the back of the bus—all with more complicated drive lines and gearbox positions.

As buses got heavier, carrying more passengers, manual steering became physically difficult, and power steering was introduced. In the same vein, automatic gearboxes replaced manual in an attempt to give passengers more comfortable and consistent riding during acceleration, and power-operated brakes offered more consistent stopping.

During the oil crisis of the 1970s various methods to reduce fuel consumption were tried, including flywheels to store energy from braking and release it for acceleration. Such flywheels need to revolve at above 100,000 rpm to store significant energy and could only be mounted horizontally mid-floor to minimize the gyroscopic effect on steering.

The quest for improved fuel consumption continues, and while the compression/ignition engine remains the backbone of bus drive units, different fuels, including compressed natural gas (CNG),

liquefied petroleum gas (LPG), and biodiesel (from crops and municipal waste) are being tried in different cities, with varying results. Because none of these alternative fuels have the same energy density as diesel oil, these other systems do not offer the same energy efficiency but may be cheaper because of local tax or subsidy regimes.

Finally, new generations of hybrid systems are being tried, with the engine driving a generator, powering electric motors attached to the drive wheels, with batteries for storage/release of braking power. In total, these alternative power systems are heavier than straight diesel drive, even though a gearbox is not needed. Making a direct energy-efficiency comparison is therefore more difficult, especially if the heavier drive means a smaller passenger capacity.

Types

Not only has the power train of buses developed significantly, so too has the form of buses. The rigid single- or double-deck bus on two axles, usually 40 feet (12 meters) long weighing about 10 tons, has developed into longer rigid three-axle buses, with two drive axles and one steering (15 tons). The ultimate is the four-axle 50-foot/15-meter rigid double-decker, with two steering and two drive axles (20 tons). Such long rigid buses can only be used on bus routes that are almost straight, since turning corners is difficult. The single- or double-deck variations reflect local operating conditions and whether most passengers expect to sit for the bus journey.

Double-deck buses need stairs between the lower and upper decks. Originally, a single stair was at the back next to the loading platform. When boarding was transferred to the front of the bus, the stairs were moved, usually to behind the driver, sometimes ascending from front to back, but mostly the other way round, because on hard braking, passengers on the stairs are thrown against the stairs rather than down them. As double decks got larger, many operators adopted two sets of stairs, one for ascending and the other for descending, to allow nonconflicting passenger flow through the bus. While double-deck buses have many more seats than single-deck buses, the stairs reduce the available and useful space on the lower deck, which is most accessible to passengers with mobility impairments.

Articulated buses are two-axle rigid buses pulling a single-axle trailer, linked so that passengers

can walk safely between the two parts. The first generation of articulated buses had the engine mounted under the floor of the front section. Later, as lower floor designs emerged, the engine was moved to be mounted vertically at the rear of the trailer section, driving the single trailer axle, or sometimes both the trailer axle and the front-section rear axle. Driving just the trailer axle requires that special attention be paid to the articulation mechanism to prevent the trailer section from jackknifing. These articulated buses are usually 60 feet (18 meters) long and 16 tons and have almost the same maneuverability as a rigid bus but with a wider swept path.

More recently, two trailer sections now follow a lead rigid bus, all linked internally as one vehicle 75 feet (19 meters) long and 20 tons, but unless one or both of the trailer axles steer, this double-articulated bus has a very wide swept path on turning, restricting it to nearly straight routes. For all varieties of articulated buses, routes and depots are needed where the buses are able to travel forward, because reversing is difficult, and even with anti-jackknife safeguards buses can be seriously damaged when trying to reverse.

The adoption of doors on buses to replace a rear open platform led to the development of an operating mechanism and then to revised arrangements. On buses with a two-man crew, the conductor operated the door. As one-man operation became universal, the driver took over responsibility for the door. Most buses have two or more doors, depending on the fare collection system. Where an off-bus revenue system is used, doors can be used for both boarding and alighting.

On single-deck rigid buses, three doors are the norm—one at the front, one in the middle, and one at the back—to ensure even loading at peak times. On articulated buses, there is a door in each trailer section. For those bus systems where drivers still collect or check fares, all passengers board at the front, and in many cases alight at the front, with only a single door provided. This means that the time spent at bus stops is a significant part of the scheduled time, leading to a slow operating speed.

At present, with the size of wheels, engine, gearbox, and transmission, it is not possible to build a bus with a significant “low floor” area. Normally, a compromise is a slightly higher floor with raised curbs and a retractable “bridge” to provide stepless

boarding and alighting of passengers, for example, in wheelchairs, though more frequently used by parents with baby carriages. The deployment of the “bridge” increases the stop time and therefore the bus journey time.

Operation

Bus operation neatly falls into two parts: route structure and revenue collection. Some bus networks attempt to provide service on many origin–destination routes without the need for changing. Inevitably, this means low-frequency services and therefore attracts those who have no alternative travel options, except taxis. Those with cars value their time too highly to depend on infrequent bus service. In other cities, less complex “few to few” routes are run at higher frequencies, typically five-minute intervals. “Turn up and go” bus services attract more of those with travel options, especially if the routes target the most heavily used travel corridors. Such networks also provide for “many to many” options by means of interchanging, and purpose-designed interchanges can make this an attractive option, especially when coupled with high-frequency connecting services. In cities where buses literally provide for a very small proportion of travel, less than 5 percent of all local travel, as in many U.S. cities, then infrequent routes can be timetabled to meet simultaneously at a downtown interchange station, to enable “many to many” journeys to be made using a “few to few” route network.

This leads to revenue collection. Those networks where a separate ticket is required for each journey have fewer interchange trips, since there is a financial penalty on interchange. An increasing number of cities now sell access to the whole network rather than to individual routes. This means that interchange trips can be made without financial penalty and, indeed, encourage the maximization of network use, on the basis that additional bus trips have a zero marginal price to the passenger. For the operator, such additional trips, provided there is spare capacity, also have nearly a zero marginal cost of provision. In many cities bus fares are set politically, without reference to market conditions or revenue maximization. This requires subsidies to cover the difference between low revenue and the high cost of providing a politically determined network. This also means that

the operator’s role is effectively that of a network manager, with few incentives to maximize either ridership or revenue.

Passenger Facilities

Many bus systems are based on the majority of passengers standing on most trips made. Where passengers have no alternative travel options this is accepted, even though it can be uncomfortable to stand in a swaying and jerking bus. Where passengers have travel options or journeys are relatively long, most passengers expect to sit. Maximizing the number of seats then becomes a key feature of bus design.

In many cities vandalism seems to be a factor in providing and maintaining seats, so hard wooden or plastic vandal-proof seats are often the norm. This is not an attractive passenger offer, even though vandal-resistant textiles are available. For safety reasons, few buses have sideways mounted seats, because in emergency braking situations passengers can be catapulted toward the front of the bus, with exposure to injury. So seats are usually forward facing, and sometimes rearward.

Similarly, hand holds, steps onto the bus, and other requirements can make boarding and alighting easier or more attractive, especially for the elderly or infirm, who in many cities make up a significant proportion of ridership. How can passenger “luggage,” such as shopping bags or baby carriages, be accommodated? In some cities hooks on the front of the bus allow baby carriages and bikes to be carried, although at the cost of extended stop time while the item is hooked on or taken off, with driver supervision.

Marketing and Presentation

Compared to other consumer products, the marketing budget of most bus services is trivial, and compared to motoring, gas, and other driving products virtually nonexistent. In most cities most residents are unaware of what bus services are available and where buses operate. Very few bus companies collect passenger or nonpassenger views about buses before new buses are ordered. Usually new buses are purchased to satisfy supply-side issues, with perhaps a token gesture to the needs of passengers.

This similarly applies to the livery of buses, often chosen by committees of politicians with little or

no reference to passengers. Some bus manufacturers conduct market research on passenger expectations but usually in the locale near the plant rather than in the city of the purchasing agency. While better marketing and advertising can raise awareness of bus services, this is no guarantee that use will increase.

Safety and Passenger Comfort

Most countries have minimum standards for the design and construction of buses, principally to ensure the safety of passengers and operating staff. Rarely are passengers consulted about the internal design or appointment of new or refurbished buses in relation to ease of boarding and alighting, comfort of seats, or the ease of getting in and out, whether seats should be bench or individual, hand holds, internal décor, etc. Fold-down seats can be used to provide more seating off peak, when generally less mobile passengers travel, and in the peak folded away to increase the space for standing passengers. Rarely is this discussed with passengers.

If the bus industry is to regain market share, consumer preference studies at least as detailed as those used by car manufacturers are needed. As most bus services are publicly funded, this would seem to be an unlikely line of development. So can bus services only look forward to a regime of managed decline, within the budget constraints of public funding bodies?

Economic Issues

If car users can be persuaded to ride buses along busy urban roads instead of driving, there would be less congestion and less environmental impacts like pollution and noise. Buses make better use of road space; typically a bus can carry 60 passengers, occupying the same space as three cars, which on average carry only four passengers, with a maximum of 12. Freed-up road space could be reused for other, more socially beneficial uses, like trees, cycle tracks, etc. In democratic societies such transfers from car to bus cannot be ordered. Even financial inducements like downtown parking charges, congestion charges, road tolls, or special car licenses are not enough to make a meaningful switch achievable. In this reorganizing of the urban economy, bus design is a relatively cosmetic issue compared to the more fundamental one of citizens' views of the role of buses.

Energy Issues

Buses are heavy users of fuel, although more efficient than the equivalent number of cars needed to carry the same passengers. However, this analysis is only valid if buses carry passengers. Empty buses are wasteful users of fuel. This is one reason why some operators use minibuses for periods with low passenger demand. As oil becomes too expensive to burn, fueling buses will be a critical issue, which even if the state operates a rationing system favoring buses, will still result in fuel becoming a major operating cost.

Bus Design for Accessibility

Transit users with special mobility needs could face transport-related social exclusion if a universal design philosophy is not fully embraced for improving the bus passenger experience as a whole. “Universal design” refers to providing transport in terms of vehicles, infrastructure and services that would efficiently provide people of diverse mobility requirements with equal opportunities to access their desired destinations. Therefore, accessible bus design, besides fulfilling the basic bus user requirements, needs to accommodate wheelchair users, people with visual and hearing impairments, cognitive-challenged people, people walking with difficulty using some form of aid such as a cane or walking frame, older people, parents with strollers, children, pregnant women, people with temporary accident injuries, even people carrying heavy baggage.

Inclusive Bus Design

For many years, buses have been designed to cater mostly, if not solely, to the needs of the average road user, who usually is a younger, physically and mentally competent traveler commuting to and from work. This is not the case anymore, as providing public transit accessibility for people with reduced mobility is legitimately enforced almost everywhere in the world.

The most important principle toward providing a bus experience that fulfills the criteria of inclusive design is to offer all necessary means of access so that a mobility-challenged user can easily enter and exit the vehicle. There are two types of gaps relevant to bus accessibility that need to be bridged so that even wheelchair users, who are the people facing the greatest barriers when accessing or alighting a bus, could be satisfied: (1) the vertical gap, which is the difference in height between the vehicle floor and the pavement at the bus stop, and (2) the horizontal gap, which is the horizontal distance between the edge of the pavement and the vehicle floor.

Conventional, or high-floor buses, can provide boarding-assisted access through use of wheelchair lifts. These elevating mechanisms have been employed in the past, but the considerable cost and the unreliability of their use made this choice unattractive for bus fleets, especially in Europe. Today,

The interior of a special bus designed to accommodate multiple disabled riders and wheelchairs seen near Prague's central Florenc bus station in the Czech Republic in April 2010.

it is widely acknowledged that buses employing low-floor technologies could provide a more reliable and cost-effective accessibility answer and are the vehicles most appreciated in the current bus market.

Low-Floor and Kneeling Buses

A low-floor bus is a bus that, between the two doors (usually at the front and in the middle), has a vehicle floor sufficiently low and level enough to eliminate the requirement for steps in the aisle both between these doors and in the vicinity of the doors. In order to put this into context, one has to compare the key design specifications that define a low-floor bus with those of a traditional bus. The floor of a traditional bus is flat and continuous and is approximately 35 inches above the street. Access to the floor level is provided by stairs at both the front and rear doors. The floor height of a low-floor bus is approximately

15 inches off the street between the front and rear doors. The floor area over the rear axle is raised, and access to this area is available either by steps or by a ramp in the floor.

Low-floor buses provide a relatively large area without seating (or seating that folds up) next to one of the doors, where wheelchairs and strollers can be parked. When there is no wheel-oriented externality on board the areas can allow high occupancy for passengers who are standing. Priority seats for seniors and disabled passengers are not designated in the wheelchair location but in close proximity to the low entry door. The position of the wheelchair usually faces the rear of the bus, resting against the bulkhead. Safety requirements are met by this concept since no accident to a wheelchair occupant has been reported on a city bus.

Usually there is a strict restriction allowing only one or two wheelchairs or pushchairs on at the same time in order for them to be accommodated while unfolded. This is for safety reasons. The most common occupied adult wheelchair is usually 43 to 47 inches in length and 24 to 28 inches in width and is about 19 inches longer than an unoccupied wheelchair. According to the International Organization for Standardization (ISO) the smallest turning circle of a wheelchair, including footrest, is, in practice, 6 feet.

Low-floor buses provide user-friendly access through a boarding assistance system either with the use of an extendable ramp that provides nearly level entry or with a kneeling system, usually based on air-suspension. A low-floor bus that is defined by its hydraulic or pneumatic kneeling device is known as a kneeling bus. This feature allows the driver, when the vehicle is not in motion, to actually lower the bus to the curb surface, making entering and exiting a much easier process for everybody, including mobility-challenged passengers. Depending on how close to the curb the bus can be parked, this system can allow wheelchair users to board unaided. The kneeling bus has no steps in its cabin to impede traffic. Passengers who use wheelchairs, as well as any passenger with mobility limitations, can navigate the entrance of a kneeling bus much more easily than a conventional bus. The main disadvantages of a kneeling bus are time-delay problems because the process of boarding takes longer, vehicle durability because the kneeling operation generates wear and tear on the bus's suspension, and excessive fuel

consumption because extra fuel is used for operating the kneeling device.

Sometimes the accessibility of a low-floor bus is enhanced by the bus stop pavement design. Specially raised sections of curb could allow easy access to some low-floor models, although this is an expensive alternative that may only be feasible for very frequent and popular routes and cities committed to inclusive design and modal shift initiatives.

Bus Engines

Mass transportation depends on a reliable system utilizing vehicles that can transport individuals and materials to and from destinations. Buses are an important mode of transportation. From a yellow school bus to a bus in a major city, these elite people movers make the world mobile. Like the human body, the propulsion system (engine) needs energy to work. The energy for a bus comes in the form

of fuel. Depending on which type of engine is used by transit agencies, the fuel must be designed specifically for the bus. Currently, buses utilize three different types of fuel: diesel, liquefied natural gas (LNG), and electric.

In the beginning, diesel engines were the cheapest and easiest manufactured in the United States. Diesel engines use diesel fuel to keep the engine running smoothly. Because of technological advances, other sources of fuel for buses have changed the way transportation departments fill up the tanks. These two types of fuel are LNG and electric.

Diesel

For thousands of students who have pulled into the school lot safely in the sea of yellow buses or a group of senior citizens embarking on a trip to the casino in the comfort of a climate-controlled bus, diesel fuel helps make these excursions possible.

Diesel fuel is cost effective and provides roughly 2 to 3 miles per gallon. Also, the cost of a diesel-engine bus is \$300,000 whereas a gas-engine bus costs \$30,000 more. While the cost and fuel efficiency may be attractive to keep buses on the road, the emissions from diesel fuel have created a strain on the environment. Alternatives to diesel fuel have been changing the newer fleets of mass transportation that are hitting the streets, especially in towns that are in a constant chokehold of smog and other pollutants.

LNG

Besides diesel, natural gas has been used as fuel for buses. Since natural gas is flammable, there has been a concern that the gas will cause an explosion. Due to this concern, an alternative to the use of natural gas has been developed. This alternative is liquefied natural gas, referred to as LNG. This type of fuel is extracted as a clear, colorless gas that does not produce any odor or corrosive or toxic substances. The conversion process from natural gas to a liquid is called liquefaction. This process involves taking the methane portion of the gas and cooling the substance to minus 259 degrees F, which takes the gas to below its boiling point. Upon completion of this process, concentrations of hydrocarbons, water, carbon dioxide, oxygen, and sulfur compounds are extracted and removed from the gas, thus decreasing the amount of emissions polluting the environment. Since LNG is in liquid form, it is half

the weight of water, causing LNG to float on top of water if the LNG is exposed to standing water.

LNG comes from major gas reserves in Algeria, Australia, Brunei, Indonesia, Libya, Malaysia, Nigeria, Oman, Qatar, and Trinidad and Tobago, and is transported to import sites in the United States—California, Massachusetts, Maryland, Georgia, Louisiana, and Puerto Rico, a U.S. territory. Within the state of California, there are over 40 LNG terminal locations that are near major roadways. When LNG is received at the terminals, it is placed in insulated containers that are specially designed to keep the LNG cool so it will not evaporate. A terminal LNG site can cost over \$1 million. LNG is used for vehicles that have a Class 8 (33,000–80,000 pounds weight) rating.

Transport systems that are looking for an alternative way of fueling buses will benefit from the use of LNG because it is easy to transport and costs less than diesel fuel or natural gas. Also, LNG produces low emissions and NO_x in comparison to the high emission rate of diesel fuel.

Electric

As diesel fuel and LNG are key components in keeping buses at the top of the world's transportation system, another means to keep buses humming on the roadways is use of electrical power. Electrical power fuels buses by the use of rechargeable electric batteries. One transportation system using electric batteries is in California along the Foothill Transit Route 280 through Azusa. Once the charge is depleted, the buses are recharged in stations during a scheduled off-duty time. A drawback to the electric battery system is that the bus routes are shorter because the buses have to get several charges throughout the day; a charge is only good for 200 to 300 miles.

Operating like the electric battery system, another fuel alternative has been created by the use of hydrogen. Hydrogen fuel cells are cheap and do not produce any pollutants except heat and water output. Unfortunately, technological problems as well as the lack of available hydrogen charging stations will likely keep this alternative from being a popular fuel choice for buses.

Diesel-Electric Combination

In addition to the standard propulsion systems for buses, a new propulsion system has been created for a hybrid bus that runs on a combination of

diesel and electric. Just like a hybrid car or truck, the hybrid bus starts with the diesel engine and changes to an electric engine when the vehicle begins to reduce down to a coasting speed.

Cheaper than a diesel-engine bus, the cost for a hybrid-powered bus can range from \$100,000 to \$200,000. Diesel-electric fueled buses are better on fuel than diesel- or gas-powered buses. However, the diesel-electric buses create more pollutants than regular electric-powered buses. Due to being efficient in cost and fuel economy, hybrid buses have been an excellent choice for transportation departments.

As environmental concerns and the increase in fuel prices affect how mass transportation can meet the demands of an ever-changing world, transportation departments must be diligent in determining which type of fuel will be used in their buses.

Bus Information Systems

One way to increase ridership on public transit systems is to improve the quality of the user experience. Because many passenger complaints center

on the uncertainty of using public transit, particularly bus systems that operate on the same roads as automobiles and thus are particularly subject to traffic delays, providing accurate information about the arrival of the next bus at a particular stop goes a long way to removing that objection, even if it cannot remove the uncertainty itself. Bus information systems have been implemented in many cities around the world and have been shown generally to improve rider satisfaction and sometimes to also be associated with an increase in ridership.

Psychology and Technology

Many people find waiting with uncertainty particularly tedious, and studies have found that the lengths of waits are often overestimated when a person does not know how long a wait will last. In the case of bus systems, an additional factor of perceived safety may intensify this experience, as people may be reluctant to use the bus system at night if they are uncertain how long they may have to wait in a dark area that they perceive as potentially dangerous. Providing accurate information about the expected length of a wait, whether by a range of minutes or by a countdown format, has been shown to reduce this overestimation of wait time. In addition, this information allows people to judge when they need to be at the bus stop, and thus when they need to leave their house, whether they have time to run an errand before getting on the bus, etc.

The roots of today's real-time bus information systems lie in technology developed in the 1980s and 1990s to allow transit systems to track the location of their vehicles. Known as automatic vehicle location (AVL) systems, this technology was first used to help transit systems increase their operating efficiency and only later was adapted to provide information to customers.

European municipalities were the first to use AVL systems to provide customers with real-time bus arrival information. The first INFOPOLIS survey, conducted from 1996 to 1997, described over 50 European transit systems supplying real-time information to passengers; the second INFOPOLIS survey, conducted in 1998–2000, described over 150 such systems operating in Europe. By way of contrast, as of 2000 in the United States, just 88 transit systems were using AVL data to supply real-time information to their passengers, although

another 142 systems were in the process of developing such programs.

Most real-time bus information systems use GPS (global positioning system) AVL systems to locate vehicles, while some use signpost and transponder systems or other methods. In any case, vehicle location information is combined with operations data (e.g., the travel time between two bus stops, based on the last several trips on a particular route), information about current and past traffic conditions, etc., to estimate vehicle arrival time at a particular stop. Some systems provide additional information, such as the time to the next few stops. Algorithms are used to make this estimation, and different transit systems use different models, based on their needs and the characteristics of their operating environment. In addition to providing arrival information, most transit systems regularly monitor the accuracy of the information provided, so adjustments can be made to the algorithms necessary; unfortunately, such monitoring often drops off the longer a system is in service, thus potentially reducing the benefit of the program by providing inaccurate information to customers.

To communicate arrival information to passengers, early systems used signs at bus stops, usually incorporated LED (light-emitting diode) or liquid crystal displays to show current information about the expected arrival of the next bus. More recently, this information is also being made available on the Internet and on mobile devices (e.g., mobile phones); only the latter are used in many recent systems, thus avoiding the costs of constructing and maintaining electronic signs but with the disadvantage of not making arrival information accessible to people who do not own the type of device required. In general, bus information systems improve customer satisfaction, and users often perceive that the transit system has improved, and some systems have also seen increased ridership.

Case Studies

Kari Watkins and colleagues studied the OneBusAway traveler information system in King County, Washington, in 2010, focusing on the area in Seattle around the University of Washington. They found that providing arrival information lowered real waiting time for passengers by 31 percent (meaning their actual wait was shorter, because they could

more accurately plan their arrival at the bus stop) and also lowered perceived waiting time. In addition, better information about bus arrival time was seen as being more important to users than service frequency and also compensated somewhat for buses going off schedule (meaning passengers were less concerned about a bus being late than the fact that they did not know it would be late).

Whereas those without arrival information tended to overestimate the time they spent waiting by almost a full minute, those provided with the arrival information estimated their wait time much closer to its actual length. Those using the OneBusAway program also expressed higher satisfaction with the public transit system and used the transit system more frequently. The OneBusAway system required passengers to access information through mobile phones, and the authors suggested that although the OneBusAway program was successful in its goals, that same information needed to be provided through other means for those who did not own a mobile phone.

Lei Tang and colleagues, studying the Chicago Transit Authority (CTA) system from 2002 to 2010, conclude that the CTA Bus Tracker, an on-time information system, was responsible for a modest but significant increase in ridership, after controlling for many other factors including gas prices, unemployment, and weather conditions. They also found that the increase was greatest on the bus lines where the CTA Bus Tracker system was implemented later (over the entire system, implementation took place between 2006 and 2009) and suggest that this may be due to diffusion of information, whereby potential riders were more aware of the system later in its implementation.

Bus Priority Lanes, Exclusive Right of Way

Buses operating in priority lanes that are located within an exclusive right-of-way (often referred to as bus rapid transit, or BRT) represent the highest order priority treatment for non-fixed route transit. These lanes are permanent physical elements within a transport network, often collocated with a general traffic corridor, that permit buses to avoid congestion, maintain a consistent and reasonable operating speed and keep to a timetable (that is, operate reliably).

Bus priority lanes within an exclusive right-of-way avoid interaction with traffic entirely, rendering the highest operating benefits. General traffic is typically excluded through physical barriers separating the priority lanes from adjacent traffic lanes, and entry to the priority lanes may be controlled through transit-actuated gates and/or "sump busters." This style of bus priority can be a precursor to development of light rail transit (LRT).

BRT is most effective as a line-haul transit solution, more akin to heavy rail where there is typically

significant separation between stops. This is in contrast to traditional bus services where routes tend to weave through local communities and there are frequent stops.

Urban Transport Systems

Urban environments are increasingly under pressure for transport infrastructure to be used to its fullest potential. Historically, this has been in the form of increasing lane utilization such as through the introduction of clearways at peak times or contraflow lanes. While these measures are effective in increasing corridor capacity, they do not specifically benefit transit services and do not encourage a shift from private vehicle to transit, which is on the agenda in many cities.

The introduction of BRT can increase significantly the capacity of a transport corridor where there may be limited opportunities for road widening and adding additional road space. This is because buses can carry far more passengers than private vehicles per operating traffic lane, all things being equal.

Recent peak hour surveys undertaken on a busy inner-city corridor connecting the central business district and a major university in metropolitan Perth, Australia, identified an average occupancy of 1.2 persons per private vehicle. The average bus occupancy in the peak hour along the same corridor was approximately 40 persons per vehicle.

In urban environments, a lane of traffic has a saturation flow of up to about 1,900 vehicles per hour. Applying average vehicle occupancy of 1.2 persons per vehicle, the theoretical capacity of the lane would be 2,280 people (assuming that the lane is solely used by private vehicles). In comparison, a bus service operating at a frequency of one vehicle per minute with an average occupancy of 40 persons per vehicle could move the same number of people.

The warrant applied by the Public Transport Authority of Western Australia is for a minimum of 10,000 passengers per day to utilize a BRT corridor for the investment to be justified. On busy corridors in some cities, this minimum threshold can be surpassed considerably. Caracas, the largest BRT corridor in Bogotá, Colombia, carries up to 45,000 passengers per day (two-way).

The most significant benefit of the exclusive lanes is that they provide the greatest degree of certainty of travel time for patrons. This is because rolling stock does not mix with and get delayed by

other modes of transport. This is key differentiator of BRT from semi- or nonexclusive bus lanes along a corridor where vehicles can legitimately enter a bus lane when making a movement to/from a side street or driveway.

Exclusivity, the defining feature of BRT, can provide a high degree of route legibility for users. However, it can also present challenges in terms of implementation. In order to achieve physical separation, significant investment often needs to be made—particularly if the system is grade separated—and the effects on the connectivity of the transport network for other modes of transport can be severely curtailed. Accordingly, BRT may be an appropriate treatment along major transport corridors but is less likely to suit a highly urbanized context where place activation and network permeability are important.

Segregating BRT From General Traffic

BRT systems either have continuous segregation from general traffic at-grade or are grade-separated from general traffic. At-grade continuous separation can be in the form of curbing or barriers. Cross movements by general traffic have to be facilitated through installation of under- or overpasses. Given the costs associated with these crossing treatments, they are typically spaced some distance apart (e.g., 2 to 3 miles minimum) at arterials rather than lower-order roads.

Grade-separated systems may be in tunnels, cut, or elevated, or a combination of the three. Accordingly, no further physical treatments tend to be needed to prevent general traffic from intruding into the lanes. However, gates are required to limit entry to the system. Often, such entry systems are triggered by a GPS transponder on board buses when they are on approach.

Dimensions of Exclusive Rights-of-Way

The width of the right-of-way varies depending on the dimensions of rolling stock, the number of operating lanes required, and the type of physical separation that is employed to prevent intrusion by general traffic. In locations where there are high tidal flows, lanes can be allocated dynamically in peaks, reducing the overall lane requirements.

Where lanes are adjacent to high walls or barriers, a minimum buffer of 1.5 feet (0.5 meters) should be provided, measured from the vehicle's mirrors.

This is to create a safety margin to assist drivers and becomes more important at higher operating speeds. A typical lane width is 12 feet (3.5 meters), which is the standard used by authorities, including Western Australia's Public Transport Authority.

A minimum vertical clearance is required through tunneled sections and along routes where there are overpasses and other overhead obstructions. Again, the minimum standard depends on the rolling stock that is used, but a 15- to 16-foot (4.7–5-meter) clearance is typical. Such a clearance can also permit use of the BRT system by other vehicles when necessary (for example, emergency services vehicles) and facilitate conversion of BRT to light rail, if desirable in the future.

Numerous other minimum and maximum design requirements apply to BRT systems, covering variables such as cross-falls and super-elevations, inter alia. The American Public Transportation Association (2010) has published guiding material in this regard.

King George Square Station in Brisbane, Australia, is sunk beneath land development. Use of either elevation or tunneling may allow integration with development and reduce at-grade general traffic congestion and interchanges.

Land Use Requirements and Cost

Land use requirements depend on whether BRT is constructed at-grade or is grade-separated. Exclusive bus lanes constructed at-grade tend to have the most significant land use requirements. Devices to separate the bus lanes from general traffic lanes and prevent intrusion by unauthorized vehicles add to the width of the corridor. Furthermore, in locations where road crossings are required, structures are needed to grade separate the roadway and bus lanes. Aside from the costs associated with these structures, additional land may be required if ramps are needed to permit buses to access the wider road network.

Where exclusive bus priority lanes are elevated, land requirements can be minimized whether the bus system sits on a deck above land use or the road used by general traffic. Elevation can permit BRT to take direct routes rather than follow defined infrastructure corridors.

Elevated systems are expensive relative to at-grade solutions given the structures required. Moreover, such systems generate noise and light spill and visual impacts. On these bases, the travel time benefits associated with elevation need to be weighed against negative impacts on amenity and capital costs. Tunnels offer similar flexibility to elevated systems without the same visual, noise, and light spill impacts. However, they are considerably more expensive again to deliver, all things being equal.

The Brisbane Bus Rapid Transit system in Australia has sections at-grade, elevated, and in tunnels. The primary reasons for elevation and tunneling (in selected locations) are to avoid at-grade general traffic congestion and interchanges, integrate with development, and permit more direct linkages between urban centers.

Implications

BRT is intended to move large numbers of people efficiently. This makes it an attractive system within a congested urban environment. Nevertheless, providing a high degree of exclusivity for bus services at-grade—being the cheapest way to deliver BRT—requires that access to the corridor by other modes is reduced. This can create a less permeable network. General traffic can be concentrated on fewer routes, adding to congestion issues and impacts on amenity for properties along these routes. Critically, the loss of permeability and added congestion can

affect local feeder bus services, necessitating added priority treatments such as queue jump lanes.

The reallocation of road space from general traffic and added congestion that can result from reductions in permeability may be part of a deliberate planning agenda. If trips by private motor vehicles (especially in peak hours) are made less attractive, greater use of the BRT system can be leveraged.

In practice, impacts on local traffic and accessibility require detailed investigation and need to be contrasted with the benefits associated with BRT. This analysis should include macro-scale modeling to understand changes in key metrics, such as trip lengths (measured by vehicle kilometers/miles traveled) or travel time (measured by vehicle hours traveled). A scheme that leads to higher travel metrics could be counterproductive if an intention of the BRT project is to improve local air quality.

The impacts of BRT on accessibility for pedestrians and cyclists also require close scrutiny. For example, pedestrian crossings need to be clearly signposted, and located along key intersections and may require grade separation or barrier/gate control (if located at-grade). On busier systems, at-grade pedestrian crossings should not be constructed because of safety reasons.

Stops and Stations

BRT stops and stations tend to take on characteristics of LRT or metro rail rather than suburban bus stop facilities. This reflects the high patronage of the system and the need for a quality boarding and alighting experience. Per the Brisbane example, busier stations in urban centers, particularly where they are integrated with land use, can be sunk or elevated so boardings and alightings are as seamless as possible.

Otherwise, careful attention needs to be paid to how pedestrians and cyclists access the BRT system. Furthermore, feeder bus services may need to interchange with BRT in certain locations. The TransMilenio system in Bogotá, Colombia, features bus lanes located in the median of a transport corridor with adjacent general-traffic lanes. Pedestrians have to access the station via overpass facilities.

Bypass/overtaking facilities can be required at stations, depending on the capacity of the BRT system (for example, how many lanes are provided in each direction) and the frequency of services that use it. The purpose of bypass/overtaking facilities is

to avoid delays to express services associated with waiting for stopped shorter-haul services at stations.

Finally, the ability to load and unload passengers quickly is an important factor to achieve the greatest benefits with a BRT system. Critical variables in this regard include use of low-floor vehicles, automated ticketing systems, sufficient platform capacity, multiple doors on vehicles, and real-time information availability.

Bus Rapid Transit, Design and Engineering of

Bus rapid transit (BRT) is a recently developed low-cost bus-based alternative to metro and tram

systems. A BRT system emulates the performance and amenities of modern rail-based transit systems, including segregated rights of way, closed stations, and pre-board ticketing. However, it has major advantages over rail-based transit, including much lower construction costs, short implementation periods (one to three years after conception), accommodation of many route permutations, and flexibility to adapt to a range of urban conditions.

In the last few decades, BRT has become widely used for urban mass transit, especially in developing cities. More than 40 cities on six continents have implemented BRT systems, and at least as many systems are either in the planning or construction stages. The Institute for Transportation and Development Policy, an international nonprofit organization headquartered in New York, and EMBARQ, a program of the World Resources Institute, a global environmental think tank in Washington, D.C., have been instrumental in promoting BRT systems around the world.

History

The term *bus rapid transit* (BRT) emerged in North America and Europe. Around the world, the concept has been described by different names, including Metro-Bus, surface metro, express bus systems, busway systems, high-capacity bus systems, and high-quality bus systems. The origins of the BRT concept date back to 1937 when the city of Chicago outlined plans for three inner-city rail lines to be converted to express bus corridors. In the first few postwar decades, exclusive busway plans were prepared for several cities in the United States, including Washington, D.C., (1955–59), St. Louis (1959), New York City (1963), and Milwaukee (1970). In Europe, the first exclusive bus lanes were implemented in Paris in 1964. The first dedicated median busways appeared in Belgium (in Liege) in 1966. The first developing-city busway was built in Lima (Peru) in 1972. The creation of the first “bus-only” street was also in 1972 in London, with the closure of a city center corridor to private car traffic.

However, the development of busways did not gain momentum until the early 1970s, when the first oil crisis pressured governments to improve public transport and customers to reduce car use. Curitiba's (Brazil) system opened in 1974, marking the modern era of BRT development and contributing to the city's global reputation as an urban success story.

With the abatement of the first oil crisis, interest in public transport diminished. While the 1980s did experience the advent of the first “guided busways,” mainly in western Europe, the concept saw relatively little further adoption due to the comparatively high infrastructure cost.

In the late 1990s, the explosion of private motorization and congestion and declines in public transport ridership in developing cities, combined with the low quality of transport services provided by informal-sector minibuses, motivated the search for quick and cost-effective public transport solutions. BRT’s profile became more widely known, especially in Latin America and Asia but also in the developed world.

In 1996, Quito (Ecuador) opened a BRT system using electric trolleybus technology. In 1999, Kunming developed the first median busway system in China. Taipei (Taiwan) also developed a median busway system, with the first corridor put into place in 2001. In 2010, the largest BRT system in Asia was implemented in Guangzhou (273 kilometers, 800,000 passengers/day). In developed nations, new BRT systems were put in place in Vancouver (Canada) in 1996, Miami (United States) in 1997, and Brisbane (Australia) in 2000. In France, technological innovations produced highly sophisticated vehicles (that is, with rounded body, covered wheels, and optical guidance systems), which minimized the distinction between BRT and light rail.

However, BRT was not yet viewed as a serious mass transit option capable of rail-like service. It was widely believed then that BRT could serve only a niche market of small and medium-sized cities or a few isolated corridors in large cities. At a reasonable speed, BRT’s maximum capacity was estimated to be only 12,000 passengers/direction/hour/lane.

The arrival of the “TransMilenio” BRT system in Bogotá (Colombia) in 2000 radically transformed the perception of BRT around the world. As a large and relatively dense city (7 million inhabitants, 240 inhabitants/hectare), Bogotá demonstrated that BRT is suitable for megacities. As of 2011, the TransMilenio system encompassed 116 kilometers of trunk corridors and 446 kilometers of feeder routes, moving more than 2.5 million passengers per day.

Key Characteristics

Typically, a BRT system has the following characteristics: (1) segregated busways or bus-only roadways

A bus rapid transit (BRT) Metrobús in Mexico City, Mexico, in 2010. The bus is separated from other traffic by a series of concrete curbs in the street. The success of Bogotá, Colombia’s BRT system led to more use of BRT in megacities like Mexico City.

over the majority of the system’s trunk/city center corridors; (2) location of the busways in the median of the roadway rather than in the curb lane; (3) an integrated “network” of routes and corridors; (4) convenient, comfortable, secure, and weather-protected stations; (5) articulated vehicles with level access between the platform and vehicle floor at stations; (6) nodal stations and terminals to facilitate physical integration between trunk routes, feeder services, and other mass transit systems (if applicable); (7) pre-board fare collection and fare verification; (8) fare integration between routes, corridors, and feeder services; (9) entry to system restricted to prescribed operators; and (10) distinctive marketing identity for the system. Other essential characteristics of a successful BRT system are qualitative in nature and include its impacts on the citizenry, that is, a sense of community pride and confidence.

Local circumstances (that is, city size, population density, trip distribution, climate, geography,

topography, financial resources, technical capacity and knowledge, existing business and institutional structures, culture, and political will) dictate the extent to which the above characteristics are necessary or feasible to achieve within cost constraints. The Institute for Transportation and Development Policy has instituted the BRT standard, a scoring system and planning tool, which certifies a BRT corridor as basic BRT, bronze, silver, or gold, thus placing it within the hierarchy of international best practice. In smaller cities, a basic BRT system might be sufficient to meet most residents' travel needs.

Most BRT plans are a combination of rational analysis and advocacy for a certain set of solutions and interventions. They generally cost in the range of \$1 million to \$3 million, depending on the complexity and size of the city as well as the consultant fees, and can be completed within a period of 12 to 18 months.

The most successful BRT systems to date have been initiated and led by charismatic political leaders, such as the former mayors Jaime Lerner of Curitiba (Brazil) and Enrique Peñalosa of Bogotá (Colombia). Some cities have intentionally created new agencies or public companies, which bypass the established regulatory agencies, to oversee the development of a BRT project.

BRT corridors are selected based on multiple factors, including customer demand, network advantages, roadway characteristics, ease of implementation, costs, political considerations, and social equity. The likely demand for a new BRT system is approximately equal to the existing public transport ridership along proposed corridors plus a percentage of new passengers (that is, a 10 percent shift from private vehicles, depending on local circumstances). However, computer modeling (such as the EMBARQ BRT Simulator) is required for more precise estimates.

A major BRT operational distinction is between a "trunk-feeder" configuration and a "direct services" configuration. A trunk-feeder system allows smaller vehicles (feeders) to be utilized in lower density areas while the main corridors (trunks) operate with larger vehicles. Although this configuration is more efficient, it also requires more terminal transfers. By contrast, direct services use a single vehicle to connect destinations (that is, a residential area to the city center). Direct services help reduce the number of transfers required but

they are more costly. To date, most direct services have been utilized within lower quality open systems (see below).

A standard BRT lane is approximately 12 feet (3.5 meters [m]) wide, while stations are generally 8 to 16 feet (2.5–5 m) wide. A standard busway with a single lane in each direction requires 32 to 42 feet (10–13 m) of road width. A BRT system that comprises express services (with passing lanes at stations) requires up to 65 feet (20 m) of road width. Solutions to overcome roadway limitations in historical centers and business districts include use of median space, expansion of roadway width, transit-only streets ("transit malls"), fixed guideways (bus tracks), grade separation, and operation in mixed-traffic lanes.

System speed and capacity depend on many factors, including multiple stopping bays at stations, express and limited-stop services, articulated vehicles with multiple wide doorways, off-board fare collection and fare verification, platform level boarding, and optimal station spacing. To date, the highest capacity BRT system (Bogotá's TransMilenio) serves more than 45,000 passengers/hour/direction. A standard BRT system without passing lanes for express services serves a maximum of 13,000 passengers/hour/direction. Most high-quality BRT systems achieve average speeds of 15 to 20 mph (23 to 30 km/h).

In general, a BRT system costs between \$1 million and \$8 million per kilometer to construct, depending on factors such as the complexity of the street environment, the need for flyovers or underpasses, the number of busway lanes, and the need for property acquisition. This amount is 5 to 20 percent of the cost of a tram or light rail transit system and 1 to 10 percent of the cost of a metro system. International development banks, especially the World Bank, are increasingly interested in supporting BRT projects.

The business structure of a BRT system is primarily defined by the system type: a "closed system" or an "open system." A closed system implies that the corridor access is limited to an approved set of operators and a restricted number of vehicles. By contrast, an open system permits any existing operator to utilize the busway. Experience to date has shown that open systems have lower quality than closed systems and are prone to busway congestion, particularly at stations and intersections. A privately operated, competitively tendered BRT

system, in conjunction with a strong oversight role by a public agency, generally provides the optimal incentives for profit and customer service.

BRT vehicle technology options involve both the vehicle size and the propulsion system. For high-demand corridors, 160-passenger articulated vehicles are standard. Feeder vehicles from lower density areas typically range from small minibuses or vans to standard-sized buses, depending on area demand.

to fill social needs; those that exist for social needs may be unprofitable but serve some greater social benefit. Ultimately, the structure of the system, and the objectives of officials overseeing that system, will dictate what is deemed important. Regardless of the motivations of officials, foresight is a critical aspect of managing bus routes.

There are three major types of bus systems: hub-and-spoke systems, in which all routes radiate from a central point; grid systems that grant access to passengers through strategically placed lines; and flexible systems that serve as a hybrid of traditional bus systems and taxi services. No matter which system they adopt, administrators must remember that what works today may not work tomorrow. This may seem like common sense or mere proverbial wisdom, but it is backed up by top economists. City planners must be ever aware of trends and social forces within their cities so that they may prepare the bus routes of tomorrow, even if they never use them. If they do not, they risk their mass transit system becoming ineffective, along with the social and economic damage that may ensue.

The planning of bus routes is by no means a task that can be completed once, then forgotten. Planning is a dynamic process that is in constant need of revision. Studies by economists employed by the World Bank Group have consistently shown that route planning always lags changes in demand. Thus, in order to maintain operating transportation systems, administrators must be constantly revising their current systems. What works and what does not is not always clear in planning bus routes; often it is merely a matter of trial and error. There are those who contend that market forces should be the sole consideration in determining bus routes. However, while most experts agree that market forces should be taken into consideration, it is widely agreed that social forces outside profit motives should play a role when determining bus routes.

Elements to take into consideration when planning routes often include surveys, vehicle operator input, economic forecasts, traffic demand forecasts, and other relevant trends predicted within the region. It is true that some metropolitan transit systems work for decades without need of revision. However, planners should be aware that society is dynamic, and unforeseen changes could always make swift adaptation necessary.

Bus Routes

Effective bus routes are critical to the overall efficiency of any mass transit system. If certain lines are overcrowded, others can become underused and valuable resources, as well as passenger time, may be wasted. Bus routes may be laid out based on profit motives. Other routes may be put in place

Types of Systems

There are three types of planning systems that may be used in determining bus routes. The first, and most historically prevalent, are hub-and-spoke systems. In this old system that relied on one central bus station, all routes came together at a central point or station. Passengers were able to get between any two points by traveling to the central station then transferring to a second bus that would take them to their final destination. When this type of system is effective, it works because most trips are short and service buses arrive at stops frequently, thus minimizing transfer times. When this type of system does not work, it is often because regular commuter traffic and congestion are a problem and a high proportion of indirect routes create a quagmire of prolonged inefficient journeys. This second scenario is more typical in the hub-and-spoke system, which may be why they are increasingly being replaced.

Grid systems consist of a series of route networks in which routes are arranged in either a grid of interconnected lines or concentric circles with connector lines. Compared to hub-and-spoke systems, grid systems have been described as more direct because a passenger may “ride like you drive.” Thus, a passenger may travel from one part of a system to another without having to travel through a central bus station, as with the traditional hub-and-spoke model.

Flexible route systems may exist on their own or be integrated into hub-and-spoke or grid systems. Routes are planned on a short-term basis and are arranged within hours based on individual requests; for this reason, these systems are also known as “demand-responsive systems.” Flexible route systems are highly individualized and transport passengers from their origin to their destination, in contrast to hub-and-spoke or grid systems that operate on the premise that passengers must travel according to existing lines.

Whether they exist independently or are integrated into other types of systems, flexible route systems improve efficiency in areas with sparse demand. When considering efficiency, replacing large vehicles with smaller ones may prove counterintuitive. However, they provide a good alternative to running a full-sized bus to an area. As part of the flexible route system, shuttles operate much like a taxi combined with a traditional bus wherein

passengers are required to share the vehicle with others and be mindful of intermediate stops based on all customers’ needs. In this way, shuttles can facilitate transporting up to 10 passengers per hour.

Bus Scheduling

The scheduling of regular bus routes involves a number of issues in order to serve passengers efficiently and effectively, with a goal of preventing both overcrowding at one extreme and frequent empty trips at the other. As a process, scheduling follows the placement of a route and the bus stops along that route. (Some such stops may also be used for other routes, when routes intersect.) The intersection of the route with other routes may impact the scheduling process—for instance, it may be desirable to schedule buses to arrive at a

given stop a certain amount of time before another bus (or other form of transit) departs from that stop if passengers are expected to frequently transfer from one to the other. The terminus locations may also impact the scheduling, when the route is expected to be used by commuters, in which case trips need to be arranged around work hours and will probably be less frequent later at night. Conversely, routes that connect residential areas to downtown areas need to operate sufficient trips in the after-work hours in order to serve downtown businesses and in some areas may be best advised to operate late-night trips to accommodate the time when entertainment venues, restaurants, and bars close for the night.

Scheduling is also impacted by the changing conditions throughout the day that affect how long it can take a bus to traverse the route. When possible, planners avoid streets with school zones, traffic circles, speed bumps, and other traffic-slowing measures, as well—at the opposite extreme—as major arteries and high-speed streets, where bus stop placement is problematic. Total avoidance of these circumstances is not always possible or practical, and variable traffic patterns throughout the day (the dense traffic of the commute hours, the moderate traffic of the workday, the lighter traffic of after-dinner hours, as well as the impact of school zones, school bus traffic, and other temporal factors) can have a serious effect on the length of time a route may take. Extra routes may need to be added in bad weather, such as in the winter, when the general speed of traffic has been slowed enough that the difference between scheduled arrival times and actual arrival times quickly expands and distorts the schedule.

Scheduling is also affected by dwell time, the time the bus spends in any given place, whether a terminus or a bus stop. Different methods of fare collection impact dwell time, as passengers searching for exact change that must be counted by the driver take longer than passengers who feed exact change into a machine, who in turn take longer than passengers using a machine that can give change back from overpayment, who in turn take longer than passengers using cards or passes that are read electronically. For buses without on-board fare collection—such as school buses, free buses, or ticketed buses whose passengers have already paid at the ticket counter—dwell time is affected primarily by the number of passengers

embarking or disembarking at any given stop. Crowded buses can experience greater dwell times as it is more difficult for passengers to find a seat or to board. Dwell time may also be affected by passenger age and similar factors. Schoolchildren can be expected to take longer to board than adults, and routes serving retirement homes will be used by elderly passengers who are slower to move and who should be assured of finding a seat before the bus resumes motion.

Scheduling must also take headways into account. Headway is the distance (or time) between buses on the same route. On a route served by a single bus, the headway is the amount of time it takes to travel the route, plus any scheduled dwell time at a terminus. But many routes with greater ridership are served by multiple buses whose schedules are staggered, such that a bus arrives at a given stop every 15 minutes, for example. The headway of a route affects the route capacity, that is, the number of passengers who can be served by that route each day. Headway also impacts passenger wait time, which in turn can impact dwell time, and thus route time: if passengers are picked up frequently enough to reduce the number waiting at any given time, then the contribution of passenger boarding to dwell time is reduced in proportion to the reduction in the size of the bus stop crowd.

Scheduling also must account for labor needs. Buses are not autonomous. Route schedules are divided into the run cut—blocks of driver assignments to particular runs, including straight runs (in which the driver drives the route continuously for a given block of time, usually eight hours), split runs (two short straight runs separated by an unpaid break period), and trippers (short blocks of less than three hours, typically a single run of a route, such as driven by school bus drivers). Modern bus companies use software to construct schedules, but the user still needs a level of expertise in order to know how to use the software, how to establish the rules by which it will be governed, and what the needs are of the bus company and its passengers.

Bus Stops/Shelters

Bus stops, the most common type of transit stop, are an essential yet often overlooked element of safe, timely, and convenient transit service. Since bus stops are the first point of contact between passengers and the bus service, the quality of the stop environment can be as important to passengers as the quality of the in-vehicle experience. Bus stops also control the number of stops buses must make and ensure that passenger loading occurs in safe, appropriate places. Therefore, bus stop characteristics can have a significant impact on customer satisfaction, safety, traffic flow, pedestrian movement, and overall transit system performance. Although bus stops are a common fixture in the urban landscape, they vary greatly in terms of operational features, scale, placement, spacing, design elements, and passenger amenities. Despite their diversity, all bus stops should offer a suitable location, safe pedestrian access, visibility for vehicles and waiting passengers, and access for people with disabilities.

Bus stops are typically placed on the sidewalk next to the street and use the edge of the roadway for passenger loading, as distinct from off-line facilities such as transit centers, which are removed from the path of the roadway and use designated areas for passenger loading. Bus stop infrastructure ranges from simple pole and sign arrangements to basic shelters to sophisticated structures. In general, the scale of a bus stop reflects the level of passenger activity. The most rudimentary stops have no identifying infrastructure and may be known only by their description.

However, most fixed-route bus services use designated stop locations, marked with a simple pole and sign, at a minimum. Depending on passenger volumes, busier stops may include additional features such as seating, lighting, shelters, or passenger information signs. Several bus stops may be clustered together to facilitate transfer between bus routes and other public transit modes.

The highest volume stops, such as those used for bus rapid transit (BRT), may be more elaborate and have more extensive passenger infrastructure than a typical bus stop. These stops, often referred to as "stations," usually have seating and a canopy covering a portion of the platform and typically are spaced farther apart than conventional bus stops. To facilitate rapid boarding, they may be constructed with off-board fare collection areas and raised platforms for level boarding. These stations may also include amenities such as lighting, bicycle storage, ticket machines, vending kiosks, emergency telephones, security cameras, artwork, and electronic information displays.

Location

A variety of factors should be considered when determining the proper location of a bus stop, including customer safety, pedestrian access, traffic conditions, parking requirements, other transit stops and connecting services, and surrounding land use. When considering the operations of a route, including any possible constraints such as topography, operators will decide to locate a stop at either the far or near side of an intersection, or mid-block. Far-side stops refer to those placed immediately beyond a signalized intersection. Near-side stops are located at the intersection, immediately prior to the signal. Mid-block stops are located between intersections, usually in a well-defined area. Each type of bus stop location has advantages and disadvantages and should be evaluated individually to determine the best placement for the stop.

In terms of operational use, far-side stops have been found to be the most beneficial, especially when accompanied by transit signal priority (TSP), a preferential treatment for transit vehicles at traffic signals. Because TSP enables the bus to proceed through the intersection before stopping for passengers, dwell time is reduced, essentially decreasing the total travel time for passengers. Far-side

stops also minimize conflicts with right-hand turns, provide more reliable intersection clearance times, and encourage passengers to cross behind the bus, which is safer than crossing in front of it. Some advantages of near-side stops are that they remove the prospect of double stopping for both signal and passenger activity, while also allowing passengers to board and alight closer to the crosswalk. Mid-block stops minimize conflicts with intersection traffic and are most often employed when a major trip attractor is located between intersections.

The distance between bus stops has a strong impact on transit vehicle and system performance, as well as overall travel time and, by extension, demand for transit. As a general rule, bus stop spacing involves a trade-off between the convenient passenger access of closely spaced stops and the improved operating efficiency and cost-effectiveness that are characteristic

of less frequent stops. Bus stop spacing is determined primarily by the urban development context and typically ranges from 600 to 750 feet in central business districts (CBD) and urban areas between 1,000 and 1,250 feet in suburban and rural areas.

Security

In addition to allowing efficient and cost-effective transit operations, a high-quality bus stop should meet the needs of all transit passengers comfortably and safely. Passenger security at a bus stop can have a strong influence on the comfort level of patrons using that stop. Landscaping, walls, advertising panels, and solid structures can restrict sight lines and provide opportunity for concealment. To enhance security, bus stops should be constructed of materials that provide clear, unobstructed views so that waiting patrons can “see and be seen,” placed

An elaborate bus shelter with a glass canopy, stone benches, and extensive maps and signage at Boston's Kenmore station in 2013. Bus stop spacing is determined primarily by the urban development context. Spacing usually ranges from 600 to 750 feet in central business districts and urban areas to 1,000 to 1,250 feet in suburban and rural areas.

at highly visible locations that allow bus drivers to see the stop clearly and permit indirect surveillance from passing traffic and nearby businesses, landscaped with low-growing shrubbery and shade trees that preserve sight lines, and equipped with lighting to improve visibility. Perceptions of security can also be improved with regular maintenance, such as the removal of trash and graffiti.

Accessibility

Accessibility for transit patrons is another consideration agencies must evaluate. Since the implementation of the Americans with Disabilities Act of 1990 (ADA), it has been required that transit service be accessible to all individuals, regardless of disability. If a person with a disability is unable to complete a trip because circumstances make it impossible to do so (for example, uneven ground at a bus stop for a wheelchair user), the individual may access paratransit, a complementary service of public transportation in the United States. Although a beneficial service, paratransit is often very expensive per trip compared to fixed-route services. Because of this and the interest in providing accessible and convenient transportation for all individuals in a community, many efforts are made to ensure that bus stops are accessible to all people, including those with disabilities.

Universal design (also called accessible design or inclusive design) refers to bus stop designs that accommodate the widest range of potential users. Universal design standards address not only people with disabilities but also older passengers; people who are unusually short or tall; people using hand-carts, scooters, and bicycles; and passengers who may be temporarily encumbered, such as a parent with a stroller or someone carrying packages. All new or relocated bus stops must comply with ADA regulations, which include provisions for obstacle-free pathways; stable, slip-resistant surfaces; wheelchair landing pads; minimum horizontal clearances; maximum slopes; and signs that are designed for use by riders with vision impairments. However, efforts should be made to design stations that are convenient to passengers with disabilities, rather than merely meet ADA requirements.

Bus Systems, Interurban

Deceptively old-school by reputation, the bus is a mode of surface transportation that has seen repeated hills and valleys of consumer acceptance and rejection. The bus has often been utilized as a necessity; its business model in the commuting and interurban sense has frequently experienced revival during times of economic downturn, alternating with contraction during periods of general economic growth. On the horizon, however, an era of interurban bus systems expanding and improving in parallel with—and even as a driver of—economic rebound seems to be upon us.

Advantages of the Mode

Interurban bus systems in the United States have in recent decades passed through a time of consolidation and even near-monopoly in various metropolitan corridors and rural regions. More recently, however, a range of influences are providing the impetus for more imaginative and responsive operational approaches to thrive. These influences include but are not limited to overall population growth, inner-city revitalization, increasingly distant daily commuting destinations, pervasive highway congestion, rising fuel prices, economic uncertainty and constricted access to capital for major infrastructure investment, improvement of

bus engines and fuel adaptability, expanding telecommunications capacity, and synergy in digital advances and dispatcher abilities.

There are further influences of a social and political nature. These feature the impetus for environmentally sounder, or sustainable, transportation solutions among urban, regional, and national planners. Also a factor is growing pragmatism on the part of elected officials at the local level when it comes to decision making, as evidenced by many progressive municipal ordinances—enacted regardless of the dominant political party affiliation of the locality—that encourage and invest in alternatives to non-sustainable energy, transport, and building methods.

Such changes and trends are evident in many parts of the world; it is not likely accidental or coincidental that numerous innovations in interurban and municipal bus systems have first been tested and refined in regions with less disposable income, fewer readily available resources, and less material abundance. Bus system innovation has been particularly marked in some of the developing world's major cities, such as Bogotá, Colombia; Quito, Ecuador; Lima, Peru; Curitiba, Brazil; and Guangzhou, China.

Researchers have pointed to the striking advantage bus operators have compared to transit systems that require considerable time and capital investment in infrastructure. Interurban bus systems can get up and running in a tiny fraction of the time it would take a rail operator, for example. Hand-in-glove with this advantage of speed to market, bus systems also have a fair amount of route flexibility built into their mode.

Bus systems in the interurban mode have some inherent advantages over automotive transport. Among these are a reduction in traffic congestion and the collective level of engine emissions, reduction in road accident fatalities, and the more general financial, environmental, and infrastructure benefits that flow from each of those reductions. The effective value of these advantages can often be enhanced by the use of such innovations as bus-only lanes, or busways. Road capacity is effectively increased in the case of some busways to levels that match rail capacity, as measured in terms of passenger-miles per minute. This is achieved by virtue of the average bus speed having increased and the average following distance being reduced safely and reliably through proper driver training, systems maintenance, and rule enforcement.

Passengers and Operators

There are several distinct types of key users of interurban bus systems. Among these are everyday commuters, business travelers, vacationers, social groups, immigrants seeking work or new communities in which to set down roots, persons for whom air or rail travel has become prohibitively expensive, and those individuals who do not drive private automobiles for reasons that may be economically or socially derived.

There are widely divergent profiles among the interurban bus line operating companies today. Long-established national and regional powerhouses have been through a period of great consolidation and robust growth of passenger volume—only to see market share erosion set in as newer, extremely low-cost operators have stepped into most markets to challenge the majors for interurban business. This last factor has led to considerable volatility in the marketplace. Other factors increasing the uncertainty of the business model include fuel prices, changing debt loads in a noninflationary macroeconomic environment, and the game-altering technological price-shopping ability of most customers.

Insofar as local and regional markets provide the opportunities, challenges, trends, and pressures that either attract or repel potential commercial route operators, they also can be influenced by the action of public policy planners and administrators. For-profit bus line operators must have suitable incentives or they will not long offer service in a given market. Urban planners, on the other hand, often have to answer the needs of underfunded constituents of their population, as well as face the specific policy challenges of residential and commercial land development, mandates to cut pollution, or make parkland accessible, and the myriad of other municipal demands.

Other Enhancements

An additional measure to increase the performance and satisfaction levels of interurban bus systems is to adopt the flexible route approach, in which dispatchers update drivers of critical traffic conditions and advise alternate roadway paths to their destinations. This ability has grown in recent years by virtue of combining global positioning system (GPS) data, real-time traffic update services, more closed-circuit television observation of highways and key intersections, and better station-to-bus communications.

Passenger psychology plays into many aspects of the acceptance and repeat utilization of interurban bus service. In case studies of some European and American bus operators, it has been demonstrated that consumer faith, trust, and comfort levels are improved when passengers have access to information such as length of wait for arrival or departure, road conditions, weather conditions at the various destinations, safety and security measures employed, and the availability of upcoming technological and transactional improvements in the bus service systems. These seemingly emotional measures, in fact, played a demonstrable role in affecting ridership and customer retention.

This in turn has larger ramifications, inasmuch as municipal planning organizations that gain confidence in the ability of bus operators to meet expectations of the riding and commuting public will be that much more ready and able to deepen partnerships with their counterparts in connecting cities, with decision making likely to shift to the advantage of interurban bus systems.

Secondary Service

While interurban bus systems in general work when their resources and efforts are concentrated on direct travel between city centers, some demographic trends suggest that flexibility may be rewarded in cases where constellations of exurban, smaller town center, and even rural crossroads locations are incorporated into the system, even if on an intermittent basis.

Adjustable fare schedules, on-call pickup requests trafficked through central system dispatching, real-time road conditions and congestion data availability, and other advances can make this option an advantageous add-on service for bus operators. Off-peak service could be blended with these secondary and even tertiary route stops, depending on how much of the available open seating on a given bus and a given route could be reasonably expected to be filled. It is likely that such a system extension would gain in potential viability by the use of collector shuttles or vans in some of the targeted sub-destination communities.

A trial-and-error approach and sufficient tolerance for initial break-even timeline extension may both be needed in order to fully gauge the ultimate success of such service, but there are reasons to consider that offering such an ancillary

tier of service would be beneficial both financially and in terms of augmenting political influence for the inevitable negotiations that come with system review by planning authorities and with infrastructure funding request cycles.

Transit-Oriented Development

One vital component of gaining and sustaining local support for interurban bus systems is the priority of keeping an adequate portion of the planners' attention fixed on the transit-oriented development (TOD) in the immediate neighborhoods surrounding the transit stations. TOD embodies both opportunity and risk. Done right, with appropriate and reasonable levels of community input as well as buy-in from outside parties interested in freshly investing in these districts, there can be fair expectation of reaching a sustainable, gradual improvement in the area from a residential, commercial, and cultural standpoint.

Of course, the sustainability of communities and infrastructure at each of the stations and transfer nodes of an interurban bus network is not a given—indeed, the goals must be clearly enumerated and then prudently considered in every stage of planning and execution. Experienced urban planners know that development around transit stations of any type does not automatically lead to economic revival or quality of life improvements in the vicinity of a new station. Nevertheless, the city neighborhood that avails itself of the opportunity today can draw upon a wealth of wisdom gained from many like projects previously pursued in varying urban environments and conditions elsewhere.

Some essential principles or strategies seem to have been proven in cases of successful TOD. These goals and instruments are sometimes summed up as the “ABCs of TOD zoning”: active, pedestrian-friendly streets, building intensity and scale, and careful transit integration. While the rule is not “one size fits all,” some locally sensitive iteration of these concepts can help get an interurban bus system off to a strong start. Each of these can be achieved through intelligent zoning, smart infrastructure investments, and commitment on the part of city authorities to provide the staffing and upkeep necessary for long-term success.

market, as riders' only choice was walking, which for many urban trips was not practical. This "supply side" logic still pervades some transit authorities, with a take-it-or-leave attitude, leading inevitably to riders getting a car and leaving buses for good.

Supply and Demand Side Considerations

In most developed cities, buses are no longer a vital service; indeed, service frequencies are often very low (hourly), a result of decades of adjusting to declining demand, as though bus services are unable to meet peoples' aspirations. This supply side logic often ends in poorly used service or none at all, the only question being how long it will take or how long subsidies will be paid for a service carrying so few people. For instance, in the United Kingdom (UK) pensioners have free bus travel, and they make up more than a third of passengers. However, most pensioner trips are not made by bus but by car.

A demand side approach is based on market research, looking at what incentives automobile users require to take some trips by transit. This is the approach that the sellers of all consumer products adopt, both to maximize sales to existing customers and also to find new products that non-users will buy. There is a considerable body of such market research, which shows that price is not the main driver for those with a choice but quality of transit service provided.

Would improving the quality of service, going "upmarket," be the obvious way to attract riders? Sadly, further market research shows that even if a bus service could be provided that offered immediate departures from bus stops, running nonstop to the desired destination, this would only attract a very small part of auto traffic. One such study in Galway in Ireland, where buses presently carry 4 percent of all city trips, showed that such a "perfect" bus service would raise this to 8 percent, leaving cars with over 60 percent of all travel.

Land Use and Transport Coordination

Logically, if land use development and bus service provision could be coordinated, then the use of bus services would be maximized. Such an experiment was conducted in Runcorn New Town, England, built in the 1960s, where a dedicated busway linked all developments with a 40-mile-per-hour (mph) (65 kilometers/hour) frequent bus service, and the freeways were arranged so that internal trips by car

Bus Systems, Local and Express

The term *bus* is short for *omnibus*, the Latin word meaning "for all." In fact, buses in most developed countries are not for all, due to market segmentation. Buses are for "dependent" riders, who do not have the option of using a car, either because the only family car is with the breadwinner at work or because there is no car. The social characteristics of bus users are that they typically come from the poorer strata of society. This was not always the case, nor is it now in developing countries; before universal car ownership, buses operated in a sellers'

would take longer than by bus. It was confidently predicted, when it was built in 1969, that buses would carry 50 percent of all internal Runcorn trips. The best managed was 15 percent, which did not justify a frequent service, so with increasing car ownership, buses now carry only 5 percent, no better than other UK towns without an expensive busway but higher than most North American cities.

Service Quality and Fares

As most bus services are provided by public authorities, political control often sees fares as the most important deterrent to using buses and the easiest variable to change, providing public funds will allow subsidy. Most market research shows that fares are usually the fourth, sometimes fifth, consideration behind reliability, speed, frequency, and convenience. These are all service quality characteristics, changing any of which usually requires investment or extra costs. Speeds and service frequency are interrelated. If buses can operate more quickly, the

same number of vehicles and crews can perform more journeys and so offer a more frequent service.

In spite of popular myths, traffic congestion is rarely the cause of bus service unreliability, since time at bus stops is longer and more variable than time at traffic stop lines. Getting passengers on and off buses faster is, like the supermarket queue, the best way to speed up service. The fastest speed is about two seconds per passenger. Where passengers on boarding have to check fares with the driver, this time can increase to 10 seconds, which means a minimum time of 12 seconds for six passengers expands to one minute.

Boarding time and the fare system interact. Early trolleybuses had two operators, a motorman and someone to collect the fare. One-person operation in the United States was introduced in the 1920s to reduce costs, as auto competition bit. This led to replacing fares based on distance traveled with a single flat fare, which was easier to collect. There is an economic justification for flat fares, namely, that

The Runcorn Busway outside of East Runcorn railway station in Cheshire, England, in 2010. When new, the busway reached a peak ridership of only 15 percent of those making local trips, rather than the anticipated 50 percent. It suggested that even faster trip times in comparison to automobiles would not lead to a significant increase in bus use. Similar experiences were reported in Houston, Texas.

nearly 80 percent of operating costs relate to stopping and starting. The most economical part of bus operation is cruising at a steady speed. Even faster are “flash” tickets for multiride or multiday validity. Most European systems operate multidoor boarding with ticketing on the “honor” system, backed up by random checking and a high charge for riding without a ticket.

Express Versus Local Services

Most bus services stop everywhere, although many systems operate on a request basis at some stops, so that buses only stop where passengers want to board or alight. The running timetable is drawn up to all for stopping at every stop. Not all stops have the same number of passengers boarding or alighting. Some stops are busy as they coincide with places of high-density activity, such as a college. If there are enough passengers to support a frequent service, for example every five minutes, then there is a case to have an express service only stop at the busiest stops. Thus a five-minute-frequency all-stops service can be converted into a 10-minute all-stops and five-minute express service, so that the busiest stops still get a bus more than once every five minutes.

In order to make the case for an express service to supplement an all-stops service, detailed passenger origin and destination data is needed to ensure that the maximum number of passengers benefit from the faster service without disadvantaging the remaining passengers using the less busy stops.

Bus Stop Spacing

There are many theories that advocate one plan of bus stop spacing over another. Since the purpose of a bus service is to attract and carry passengers, bus stop spacing is not just an operational matter. There is a trade-off between the time passengers are willing to spend walking to a bus stop and the time spent on the bus. Walking time to bus stops is shorter when stops are close together. Riding time is shorter when stops are farther apart. Since passengers weight walking time as being twice as onerous as riding time, this would produce close stop spacing, say every 300 yards (275 meters) or so, but slower service overall. An alternative to having dedicated stops is request-only service (where the driver stops wherever there is a passenger waiting to be picked up or wishes to be let off) which would minimize walk time, and minimize ride time.

Should bus stops have pull-ins off the roadway? Such “lay-bys,” while benefitting (a few) car drivers, inconvenience bus passengers, who are delayed as the bus driver tries to reenter the traffic stream. If public policy is in favor of bus transit, then there is no case for bus lay-bys, since if the service is infrequent, few car users will be inconvenienced by buses stopping in the traffic lane. If the service is frequent, then bus passengers will easily outnumber car users.

Operation and Timetables

One other factor influencing bus stop spacing is service frequency. With a high-frequency bus service, timetabling is critical, as is the method of fare collection. A slow fare collection system will lead to buses bunching, like the supermarket checkout line problem, and thus an unreliable service. As early as 1955 studies showed that with even a two-second boarding time, if passengers arrive faster than they can board, buses bunch. More stops, close together, spread passengers and reduce the problem of bunching and unreliable service. The operating timetable must also be framed to reflect passenger numbers as well as traffic conditions, because unrealistic timetables—not enough time in the peaks and too much time off peak—lead to unreliability. Finally, driver discipline is important to maintaining a reliable service, and one of the most important factors is leaving the terminus at the right time.

Revenue Collection Systems

Revenue collection may be a matter of public policy if the bus transit service is publicly or municipally owned and must be subsidized. In the UK, where most bus services were privatized in the 1980s, 80 percent operate without subsidy on a commercial basis. Since bus passengers in developed countries are “captive” but poor, the fare system may be operated as a form of social policy, with lower than economic fare levels. Nearly all such bus services now operate on a flat or nearly flat fare system if routes are long.

A cash fare collected on boarding is the slowest method and the most costly to process, as cash has to be transported, counted, and banked. As well as advance-purchase “flash” tickets, there are now contactless bank cards, which automatically debit the fare, and cell phones can be used to buy and

display tickets. All of these reduce or eliminate cash transactions on buses, which also improves driver security since the driver cannot be robbed.

Obviously, one benchmark for setting the fare level is the cost of operating the service, which is discussed below. Another benchmark is the (perceived) price of competitor transport, such as car or taxi. Nearly all bus systems offer discounts for regular travelers. While flat fares are easy to implement and police, they do impose a penalty on passengers who have to change buses to complete their journey, unless transfer tickets are issued. This is one reason why many European bus systems sell advance tickets by time, such as one hour, one day, one week, etc.; this allows passengers complete freedom to use several buses to make a journey without facing a fare penalty, and the allotted time is easily determined and proved.

For those operators who think this represents a loss of revenue, the alternative for many passengers would be not to make the journey by bus, so there would be no revenue, and outside the peaks, when there is spare capacity, the cost of carrying passengers at the margin is very low, so the revenue received from time-based tickets should cover this.

Finally, the elasticity of demand to fares historically has been about minus 0.3, which means that fare increases have always increased revenue, since the loss of passengers has always been less than the rise of fares. Today the evidence is that elasticity is minus 0.4 or more. This means that fare increases often do not increase revenue, as too many passengers quit using the service.

Operating Costs

The largest part of bus service operating costs is staff pay, typically 50 to 70 percent of total costs. Making drivers more productive from faster services and/or larger buses is one way to reduce unit costs. In the UK where bus services have been privatized, bus companies realized that raising fares to cover increasing costs only leads to going out of business, by driving away passengers. So UK bus companies have put a lot of effort into controlling and reducing operating costs.

In a bus service with high peaks, having a standard 8-hour work shift contract is almost the most expensive way to deploy staff. So, many UK bus companies have a mixture of full-time and part-time staff to cover peak demand and fleet operation.

Similarly, some companies have diversified into minibus operation to penetrate closer to passengers' homes, providing nearly a door-to-door service. Minibuses, being more maneuverable, can also offer faster service, and because minibuses are small, new drivers do not require the same qualifications needed for operating larger buses, and therefore can be employed at lower pay levels.

Fuel costs for diesel-engine buses is rarely more than 10 percent of operating costs but still a large ticket item. Good engine maintenance can optimize fuel consumption, but probably more effective is driver training, which has been shown to reduce fuel consumption by 25 percent. Less fuel used means less polluting emissions. Some bus operators have long-term contracts with fuel companies, while others buy on the spot market but need large storage tanks to benefit from low-price times. Many operators in Europe are also experimenting with recycled lubricating and cooking oils to improve sustainability and to be a little greener. Such non-diesel fuels tend to provide fewer miles per gallon but the gallons are less costly.

Depot Location

The main fixed operating plant for a bus service is the depot where buses are maintained, repaired, valeted, and garaged overnight. For a single busline the location of the depot will usually be at the end where most journeys in the morning originate, on a site that has low value and the depot is not seen as a bad neighbor. For a multiline bus system, this will be a more complex analysis, since each line will not need its own maintenance facility and one major repair depot may be enough for a city. Overnight garaging and valeting depots may serve one line or several lines and can be located at sites of low land value that may be in an industrial or commercial zone.

Bus Station or Dispersed Stops

Where a bus network serves a region or large city, there is merit in planning for a central bus station to facilitate interchanges between routes to enable "many-to-many" trips to be made. This, however, requires bus timetables to be coordinated, so that interchanging passengers do not have to wait, which would reduce the convenience and attraction of such trips. Interchange trips, however, are likely to be a minority, even if major trip-generating and -attracting activities are evenly spread throughout

the area. The reason for this is that most trips are relatively short and long trips relatively few.

A “central” bus station will need a large ground area to allow buses to enter, stop for passengers, and depart. If there are a large number of services with coordinated timetables, then there will have to be one bus stand for each service. In providing a central bus station, the relatively low-value economic activity of bus service passenger access and interchange can be enhanced by the development of air rights above the bus station for commercial or residential use. Such overhead development will need careful design to ensure that the bus station is not claustrophobic for passengers and staff and that adequate ventilation can be provided to maintain a healthy level of air quality by dispersing bus engine fumes.

The case for a central bus station weakens if the central business district (CBD) is itself the major destination of bus trips. In this case CBD bus stops can be dispersed in the downtown, and as an operational convenience two radial bus routes linked to make a cross-town route, so that buses are not required to wait in the city center for timetable maintenance and crew rests. Where bus services act as feeders to a rail rapid transit service, this interchange can be made very convenient by integrating the rail station with a bus station, including the possibility of cross-platform interchange.

Bus Lanes and Busways

Bus lanes and busways have been installed in many cities. These primarily provide supply-side benefits, in terms of faster running speeds, less traffic congestion and disruption, and therefore reduced unit operating costs. As discussed above, a pioneering experiment in Runcorn, England, to use busways offering faster trip times than automobiles, failed to achieve the anticipated improvement in bus use. Similar experiences were reported in Houston, Texas, where a 10-year program of high occupancy vehicle (HOV) lane construction reduced transit’s modal share by 10 percent. In contrast bus lanes and busways in developing countries report high use, for example, in Curitiba in Brazil, where car ownership is lower than in developed countries. It will be of interest to see if high bus usage is maintained when car ownership reaches North American, or even European levels.

Bus Systems, Rural

Rural poverty can have a particularly debilitating effect compared to urban poverty in that it also leads to personal isolation and the inability to access public services. Those who are not poor can also suffer from these problems when they do not have personal transportation, which might occur because of health or age issues or personal preference. There is a need, therefore, for low-cost transportation to serve people in these categories and to make small-town living practical for many communities—people cannot buy products from local businesses if they need to visit the premises and are unable to do so. Rural bus systems are important in sustaining the populations in these areas and, to common with all public transportation systems, have a role to play in reducing carbon emissions and air and noise pollution.

Since speed is rarely a major factor in such services, rural bus systems can be a safer means of transportation while also being suitable for use of vehicles using renewable or low-oil sources. The problem posed for such services is, of course, the cost issue. The numbers of people wishing to use the service tends to be small and so the revenue that can be raised is limited. Further, there is a

tendency for most customers to wish to travel from their homes to a local center and back again. However, routing logistics mean that buses customarily move from stop to stop in a geographically coherent manner rather than repeatedly to and from the central point. This means journeys tend to be lengthy and meandering and makes timing problematic because the distance between stops is directly related to the overall length of the journey; if passengers at every stop are to reach the central point at a time when they can access public services conveniently, then at least some of them will have to leave early or return home late.

In an era in which private wealth is preferred to public solidarity in most of the Western world, bus services of this sort tend to be starved of funds and the level of satisfaction suffers, leading to lower usage and then more cutbacks.

Governance Systems

The standard and most typical means of organizing a rural bus system is through the public sector, not so much because road transportation is a natural monopoly as because a regular and well-regulated service aiming to satisfy all communities is unlikely to be profitable. However, especially in less developed countries, there are numerous examples of private-sector operations. These operations tend to be underregulated and passengers may be placed in unsafe conditions. In rural Thailand and Laos, bus owners—these vehicles are usually small trucks or pickup vans with two rows of seating installed lengthways—roam from village to village based on local knowledge of periodically held markets and the needs of specific local people. They collect fees in cash only and have no obligation to visit a particular route or to adhere to any specific schedule. Even quite large operations, which drive large coaches from city to city, reserve the right to vary their advertised routes to other stops or cities if drivers feel they can obtain more passengers that way.

It is not coincidental that, across the developing world, road traffic accidents involving private-sector operators take thousands of lives every year. However, this does not mean that all private-sector operations are necessarily dangerous or otherwise improperly managed. Well-regulated private-sector operations do work quite satisfactorily in many countries.

Passengers wait at a handmade wooden bus shelter outside a village on the road to Dori, Burkina Faso, in July 2010. In less developed countries, passengers may often be subjected to unsafe conditions and unreliable schedules by private operators.

Alternative governance systems also exist. In the United States, for example, some schemes enable users to provide transportation services on a barter basis, that is, offering lifts to people in one area so that other people elsewhere (perhaps aged relatives) can claim trips of their own. There are some issues to deal with concerning insurance and safety in this case and there are other ways of organizing payment on a noncash basis.

One aspect of rural service that is distinctive is that it enables repeated human contact between service providers and customers and, as a result, personal relationships can develop such that bus drivers will look out for particular passengers, giving them additional time to board and alight if necessary and even involve themselves in some personal errands. This type of relationship used to be a more common feature in the past, when delivery

people such as mail carriers might have represented an important link between people in rural settings and the wider community. These are relationships that were ended by such factors as the imposition of more stringent productivity and efficiency approaches to the work completed by people in such jobs. It has been argued that the existence and fostering of such relationships plays an important part in the production and reproduction of harmonious social relations that contribute to the quality of life for those involved.

It is because, in part, of these positive externalities that various state or regional-level government agencies have been searching for alternative means of boosting demand in rural communities, thereby helping make systems operationally profitable. In Germany, one such effort is focusing on a “call-a-bus” approach, in which passengers can order a bus to stop to collect them or to deliver small packages for them. Since smart scheduling of such a service, provided sufficient capacity is available, can take advantage of off-peak hours when demand is low, it may be able to provide door-to-door service, which contributes positively to social capital while also reducing environmental degradation and pollution. Autonomous (that is, self-driving) vehicles can be used to reduce costs, and the vehicles employed could run on less environmentally damaging energy sources such as batteries or solar power.

This system will likely become more viable if the desire for localism develops further, so that people resolve to consume food and other goods and services produced within about 30 miles (50 kilometers) from where they live. Such a development would enable bus managers to bundle more of the services currently provided by specialized firms as a means of improving triple-bottom-line efficiency (that is, incorporating social and economic impacts into the accounting process). This approach is the opposite of what has taken place since the late 1970s, when deregulation and marketization of all aspects of contemporary life have become the norm, irrespective of the broader results of such changes.

Buses

A bus is a self-propelled form of transit by road, which normally runs on a fixed route and schedule, serves identified stops, and is usually capable of carrying 10 passengers or more for a fare. Short for “omnibus,” it is sometimes used interchangeably with “coach,” although coaches tend to cover longer distances, have more room for luggage, require prepaid tickets, and have more comfortable seating. Sometimes charter bus services transport groups to a prearranged destination at a time of their selection, presenting an alternative to the fixed-route service that buses tend to offer.

Across Europe and North America, buses progressed from horse-drawn coaches and developed as a supplement to urban streetcars in the 1920s, and then eventually as a replacement. Bus networks saw a huge expansion in the 1940s through to the 1960s as a result of suburbanization, which saw the subsequent extension of road and highway networks and the demand for access to city centers and employment opportunities. They are now one

of the most commonly used forms of public transit. They are low cost and are most regularly associated with the young, students, women, the elderly, and people with low incomes. This can often include recent immigrants or ethnic minorities and as a result, bus spaces are regularly considered to be sites where boundaries of class, race, and ethnicity are “breached.” On the presentation of an ID card and bus pass, the elderly and students are commonly entitled to free or discounted travel.

Transportation by bus is often done out of necessity and is a method of travel that is often considered to be a last resort, associated with short journeys and commutes. Unlike travel by automobile, which is considered to offer more security and connotations of prestige, competence, speed, masculinity, skill, and autonomy, buses require that passengers travel in close proximity to strangers and are often considered to be both less comfortable and a slower form of travel. They are regularly associated with problems of overcrowding. In most circumstances there are no seat reservations, and although buses operate on a timetable, there are often no real travel-time guarantees. Unlike trains, for example, they are susceptible to the problems of urban congestion and are often slowed down by the need to distribute tickets to boarding passengers—although this is not the case with all services. Methods of payment vary considerably. If paying by cash, in some instances, the exact amount is required, as no change is provided in order to keep boarding time to a minimum. Passes can be purchased for a day of travel, a week, or longer and are usually shown to the driver, swiped, or tapped upon boarding the bus. Local boarding and payment procedures are likely to vary considerably and have been cited as one reason why bus travel is avoided by some people.

Contemporary buses have no conductors and there is often little space for luggage, although there is often a designated area at the front of the bus for large bags and shopping. Unlike other forms of transport, buses are likely to make more regular stops and can stop every few minutes. As a consequence, bus passenger groups constantly change and passengers might be required to swap seats as people get on and off, to allow less able passengers or people with buggies or luggage to sit near the front. Passengers wait at bus stops or bus shelters that display the number of the bus route they

require, as stops often serve as collection points for more than one bus service or provider.

In order to address the adequacy of bus services, cost and efficiency are often considered to be the key factors affecting user choices of transportation. However, in recent years, attention has been paid to the experience of bus travel in an effort to increase public use of buses beyond low-income groups. This is important to transport policy, as buses are increasingly seen as a solution to promoting more sustainable forms of transportation and to reducing the number of automobiles on the road.

It is widely recognized that bus travel can often have a negative reputation as a focal point of danger. This includes concerns about antisocial behavior from other passengers, vandalism, and also drug taking and drinking during journeys. It is commonplace for buses to have security cameras on board as well as sophisticated systems for reporting vandalism and antisocial behavior. However, due to the lack of onboard conductors and the design and layout of buses (double-deck buses in particular), it is often felt that these measures are insufficient to secure the safety of passengers. Concerns over security are particularly prevalent at night and are also associated with waiting alone at bus stops for long periods of time.

Alongside fears over security, the close proximity to other people that is required during bus travel is often considered to be another factor that makes buses an undesirable form of transportation. This includes a lack, or invasion of, personal space and the use of mobile phones and other mobile technology devices that are regularly cited as sources of conflict and annoyance. Despite frequent complaints, however, it should be noted that buses are also considered to be spaces of conversation and social connection and have been prioritized within urban public policies concerned with tackling segregation as a way of moving people between different areas.

Types of Buses

The most common form of bus travel is the scheduled route service that often operates within and between urban areas and is characterized by frequent departure times. City and suburban buses tend to have a low maximum speed, make regular stops, have maximum provision for standing passengers, and have a low provision for luggage

storage. They can be accessed from the curbside by two or one access points.

Tour buses often follow a specified circuit and may run on a regular schedule depending on the season. These can often be seen within urban areas and take tourists to key sites and tourist locations. Tour buses may be open top and accompanied by a tour guide. Some tour buses might provide intercity services and have a larger capacity for storage.

School buses transport children between home and school and are used only by school pupils. While yellow school buses are commonplace in North America, across Europe the prevalence of school buses varies, and in some countries the travel requirements of schoolchildren might be met by regular fixed-route services.

Finally, airport buses often link airports to downtowns or urban transport hubs such as train stations to enable passengers to gain access to further transport networks and to make connections for onward travel. These bus services are sometimes provided free of charge and have a much larger capacity for luggage storage and low-ride platforms. Bus design varies considerably. They can be either single-deck or double-deck, although double-deck buses are more commonly associated with urban route services. Other noticeable designs include the “bendy” or “articulated” bus, which can bend in the middle to accommodate a large number of passengers while still being able to navigate compact road networks.

Business Travel

Business travel is a significant and substantial force in the U.S. economy. One out of eight U.S. jobs depends on travel and tourism, and travel is among the top 10 employment industries in 48 states. Business travel directly sustains more employment than a host of other key U.S. economic sectors. The 1.92 million jobs created by business travel spending exceed employment in building construction, food manufacturing, computer and electronics manufacturing, telecommunications, chemical manufacturing, oil and gas extraction, and motor vehicle and parts manufacturing.

Economic Effects

Business travel alone accounted for \$249 billion spent in 2011 by domestic and international travelers in the United States. Business travel expenditures include transportation to, overnight lodging at, and food consumption during all business meetings, events (such as trade shows), and incentive trips.

Corporate spending on travel may include air and rail transport, taxis, car rentals, hotels, restaurants, and event planning. All of these and related expenditures represent the direct impact of business travel spending on the economy. Less direct—but no less valuable—is the broadening effect business travel has on company performance and productivity, as well as the longer term effects on the economy as a whole. These indirect gains may include staff and customer retention, broader customer market, employee satisfaction and performance, idea sharing, industry knowledge and growth, improved products and services, and building of corporate relationships. Not as easy to measure but nonetheless one of the more important aspects of business travel is preventing the potential loss of current customers and revenue from *not* meeting in person.

Trends and Impact

A May 2013 report from Oxford Economics, a global research firm, provided clear evidence that business travel directly leads to an increase in both corporate revenue and profits.

The study found that for every dollar invested in business travel, the return on investment (ROI) resulted in averages of \$12.50 in added revenues and \$3.80 in new profits. Trip types with the highest returns were customer meetings, followed by

conferences and trade shows. Other findings in the Oxford report indicated that although business travel declined during the 2008–09 economic downturn (during the first two months of 2009, the U.S. lodging industry alone lost more than \$1 billion in revenue from the cancellation of corporate meetings and events), business trips increased from 2010 through 2012 and were still on the rise. Data from 2007 through 2011 for 61 industries showed that sectors spending the most on business travel through the recession tended to exhibit profit growth through the latest economic cycle.

Companies depend on face-to-face meetings to close deals, to keep present customers as well as win over new business, and to develop high-performing employees. Surveys taken as part of the Oxford study showed that business travelers believe that over 40 percent of customers would eventually be lost without face-to-face meetings; they believe that prospects are nearly twice as likely to become new customers with an in-person encounter than without one. A survey of business executives at companies with more than \$50 million in annual sales found that of those surveyed, 82 percent believe that business travel is important to achieving their business results, 81 percent believe that more client contact is necessary in a slow economy, 59 percent strongly agree that in-person meetings grow their business, and 72 percent believe that increasing travel while others are cutting back creates an opportunity to build market share and new customer relationships.

Global View

As reported in May 2011 by the World Travel and Tourism Council (WTTC) in a two-pronged study, business travel over the past decade has improved global corporate productivity 10-fold and created millions of jobs worldwide. Business travel is integral to international trade, and it is estimated that one-third of global trade over the past decade has been driven by international business travel. In the first part of the WTTC study, a survey taken of 500 global business travelers and executives from the United States, the United Kingdom, Germany, Brazil, and China revealed a clear link between international business travel growth and growth in world trade. Results from all five countries indicated clear benefits in terms of new sales, increased profits, innovation, partnership opportunities, and overall productivity and efficiency.

In the second part of the study, an econometric analysis was undertaken with data covering 190 countries. The modeling tested for the existence of any causal relationships between business travel and national economic performance. Results indicated that countries with a larger level of business travel spending tend to experience a higher volume of exports. Also, faster growth in business travel is linked to more rapid trade growth.

The implications of these trade effects are significant. Trade not only generates income for companies but also advances economic development by creating operational efficiencies, lowering prices, allowing countries to gain in terms of comparative advantage, encouraging innovation and creating competition. As business travel plays a role as a catalyst of global trade, it spurs global economic growth and stability.

Concerns

While there is much data supporting all of the benefits of global business travel, this economic sector is not without some inherent difficulties. Even as national economies recover, corporations are tentative about travel spending. Virtual meeting technology, increased fuel and environmental costs, and security concerns are all influencing corporate and government policies concerning travel. As an example, in his May 7, 2013, report to the U.S. House Subcommittee on Commerce, Manufacturing, and Trade, Roger Dow, president and chief executive officer of the U.S. Travel Association, pointed out that the main obstacle presently discouraging travel (both business and leisure) into the United States from abroad is an inefficient entry process (long lines and wait times). Aviation security systems are currently developing new approaches that have a greater level of efficiency while maintaining security.

Meetings and events held both in person and online (“hybrid events”) will be increasingly explored by more companies as a way to control costs while taking advantage of social features offered by new technologies. Despite these new innovations in virtual technology, many business executives still firmly believe in investing in face-to-face contacts. In-person encounters are the foundation of business travel economics.

Busways and Reversible Bus Lanes

Busways (also known as "bus lanes") are road lanes for the exclusive use of buses. In some cases or at certain hours of the day, other vehicles may also be allowed to use the lanes. Busways are increasingly relevant in transportation policy as an instrument to reduce car use and tackle problems such as congestion, road safety, pollution, and energy consumption. Bus lanes are also implemented as elements of high-performance public transportation networks such as bus rapid transit (BRT) systems.

Despite the advantages and the increased relevance of busways in urban transportation policy, the implementation and operation of the schemes are sometimes restricted by a lack of social and political support and by problems in enforcement.

Busways were first used in Germany in the 1960s, with Hamburg being the first example. Cities throughout the world have since implemented the system in parts of their bus network. In large metropolitan areas such as London, Paris, and Beijing, the network of busways is very extensive (more than 200 kilometers long) and fulfills a crucial role in the mobility of commuters. Busway schemes have generally met with success and are increasingly considered as an essential element of programs to mitigate road traffic and improve the performance of public transportation systems.

While the system is designed for the exclusive use of buses, other vehicle categories, such as motorcycles, bicycles, delivery vehicles, emergency vehicles, taxis, and other means of public transportation are sometimes allowed to use the lanes. Buses may also share the lanes with cars traveling with more than one or two passengers in schemes known as high occupancy vehicle (HOV) lanes or high occupancy toll (HOT) lanes. In some cases, busways are open to all road traffic during off-peak periods. Some lanes may also operate in both directions depending on the time of day and are known as reversible lanes. These regulations ensure a more efficient use of road capacity in the cases when demand is highly variable throughout the day, such as in commuting corridors linking residential areas with major centers of employment.

The implementation of busways may be complemented with other preferential measures for buses in road traffic, such as the assignment of signal priority, queue bypass or queue jump, and turn restriction exemptions. These measures are applied to increase the connectivity of the lanes for the exclusive use of buses and to reduce delays in bus services by eliminating detours and stops.

Objectives

The main objective of busways is to increase the average operating speeds for buses in areas with high congestion levels. Indeed, the assessment of the effects of the scheme in cities throughout the world has consistently shown substantial improvement in the speeds of bus services operating along the busway corridors. The use of busways is especially attractive to express services, although they also bring advantages to services stopping at every bus stop, especially when structures such as curb

extensions and boarding islands are included in the design of the system.

However, the improvements in bus lanes may come at the expense of speeds in other parts of the bus network, especially when the lanes are implemented through the reallocation of existing road space. The reduction of capacity for general traffic reduces its average speeds and may force some car drivers to use alternative routes. If capacity along these routes remains unchanged, congestion will increase, affecting both car and bus traffic.

The reduction of congestion levels in bus lanes brings additional advantages apart from the effects on speed. Users benefit from the increased reliability of the services, due to the reduction of delays and lower variability in waiting times at bus stops. The operators of the system also gain financial benefits as congestion is usually related to higher fuel consumption per distance traveled due to vehicle idling time. If the improvement in the performance of the bus system attracts additional passengers, revenues will also increase.

Advantages

A series of indirect advantages have also been identified. By making bus travel more attractive, the system promotes modal shift from private vehicles, contributing to a general reduction in road traffic levels, congestion, and emission of local and global pollutants. The existence of bus lanes also contributes to a reduction in the number of fatalities in road accidents, as they act as a buffer reducing collisions between vehicles and roadside objects. In addition, the separation of bus and car traffic enhances the safety and comfort of passengers waiting for or boarding buses, as it increases the visibility of buses and increases the distance between passengers and cars.

Disadvantages

Nevertheless, busways can also have a negative impact on pedestrian safety and local environmental conditions when the implementation of the scheme involves the construction of additional lanes. The widening of the road may be achieved by reducing pavement space. This increases the proximity of pedestrians to road traffic, with effects on pedestrian accident risk and exposure to air pollution and noise. The increase in the number of lanes also affects the safety of pedestrians crossing

the road. The widening of the road may also come at the expense of existing open space surrounding the road, with indirect effects on urban environmental conditions.

Bus Rapid Transit and Other Strategies

Busways are an essential component of policies to improve the performance of urban public transit networks, such as the implementation of bus rapid transit systems. These systems share some of the characteristics of light rail or underground systems, such as a limited number of stops, frequent and regular service, and the use of exclusive corridors. The success of BRT systems in Latin American cities such as Curitiba (Brazil) and Bogotá (Colombia) has encouraged the adoption of similar systems in other cities of the world, with a large number of systems currently being developed in China and India.

A tour bus followed by a sport utility vehicle in a single-direction bus lane on Broadway in Lower Manhattan. The city of Hamburg, Germany, pioneered bus lanes in the 1960s and has since been followed by large cities around the world.

Busways are also increasingly planned as a part of broad strategies for the promotion of alternatives to the use of private vehicles. As such, some busways are designed or redesigned for the shared use of buses and bicycles. These projects can increase the efficiency in the allocation of road capacity to different means of transport. They can also decrease accident risk for cyclists by separating them from general traffic. However, the achievement of these objectives is dependent on careful design and control of several elements of the road and of the bus system, such as lane width, bus speeds, locations of bus stops, clarity of traffic signs, and design of intersections.

Reception

Despite the obvious advantages of the scheme, transport authorities do not always gather the social and political support needed for the expansion of the busway network. Car users may object to a perceived preferential treatment of users of public transportation. This is especially prevalent in cases in which bus lanes are underutilized. In addition, when busways are implemented through the reassignment of existing road space, congestion may increase considerably in the other lanes, leading to losses of time and higher fuel consumption for car users.

Bus lanes can also reduce space available for car parking and space used for loading and unloading freight. There are also conflicts over which vehicles other than buses are allowed to use the lanes. This is often the case when access to taxis is granted to a select number of taxi firms, leading to complaints

by the other firms on the grounds of distorted competition.

The system can also meet with problems at the operational level. Given the extension of most busway networks, the enforcement of restrictions on the use of the lanes is difficult and costly. Failures in enforcement may lead to reduced speeds when a large number of private vehicles use the busways, and to bottlenecks when parked cars obstruct the lanes. The problem is sometimes addressed by using barriers to separate bus lanes from other lanes. The increased use of closed circuit television can also improve enforcement by dissuading car drivers from using the busways.

Cable Cars

Cable cars are a type of railway consisting of a continuously moving cable and a number of cars that are powered by gripping onto the cable; in order to stop, the cable is released and a brake applied. In the 19th and early 20th centuries, cable cars (often called cable tramways or cable trams, to distinguish them from funicular railways, which are permanently attached to their cable) were one of several means of providing streetcar service in major cities. Advantages of cable cars include their ability to climb steep hills, their lack of pollution, and their relative impermeability to extremes of weather. However, other methods of public transportation, including electric railways and buses, eventually replaced most of these cable tram systems. The only city operating a traditional cable car system today is San Francisco, California, where cable cars are well adapted to the city's steep hills and are keeping part of the city's history alive.

Technology

A cable car system is propelled by a continuously moving cable that runs through a powerhouse, where it is threaded through a series of sheaves (wheels with grooves in their edges) powered by engines that impart the movement to the cable. The cables run out of the powerhouse and along their routes, encased in a protective steel "slot" below street level while the

cable cars run on rails above it. The cable cars have no power of their own but are moved by the cable; thus they maintain a constant speed except when coming to a stop. Several different technological solutions evolved to enable an operator to grip and release the cable, and the cars also had several braking systems to further control the speed of the cars and allow them to be halted, one advantage of the cable trams over horse railways. Other advantages include the fact that the cable system is little affected by changes in temperature or by the accumulation of snow and ice and does not create pollution on its route. (It does, of course, at the powerhouse.)

Public Transportation

The city most identified with the cable car is San Francisco, California, where cable cars were invented, and the only city in the world where traditional grip-and-release cable cars are in use today. Andrew Smith Hallidie began construction of a cable car line in San Francisco in 1873, reportedly motivated by seeing a team of horses drawing a rail car slip and fall to their deaths. He may also have been motivated by the fact that a cable car system would use large quantities of wire cable, a product for which he and his father held several patents. Hallidie's cable car network began operation that same year with a single line, the Clay Street Hill Railroad, but by 1889 San Francisco's cable car network had grown to include 53 miles of track. By that time a second company, the Sutter Street

A cable car reaches the top of a hill near San Francisco, California's Chinatown in 2006. San Francisco is the last city in the world to operate a traditional cable car system.

Railroad Company, was in the cable car business; the Sutter Street Company originally provided transportation by horsecar, but it had converted most of its lines to run on cables by 1879.

By the turn of the century, electric streetcars were competing with the cable cars, although the steep topography of San Francisco gave cable cars an advantage on some routes. Cable cars were almost eliminated from the city in 1947 due to their higher operational costs relative to other forms of transportation but were eventually retained, in part because of their tourism value.

Sydney, Australia, included a few cable cars in its public transportation to provide transportation over particularly steep routes. However, Melbourne was the only city in Australia to create an extensive network of cable cars; the Melbourne system was the fourth-largest in the world, with about 75 kilometers of track, and operated from 1885 to 1940. Each tram consisted of two cars: a standard passenger car and a forward car called a "dummy," which pulled the second car; the driver, who operated levers to grip

and release the cable, rode in the dummy car. After the state government took over the system in the 1920s, Melbourne's cable trams began to be replaced by electric tram lines, and the last cable tram ran on October 26, 1940. In New Zealand, the cities of Dunedin and Wellington also had cable tram systems that are no longer in operation.

Many other cities operated cable tramways in the late 19th and early 20th centuries, usually alongside other forms of public transportation. Edinburgh, Scotland, had an extensive network of tramways that included cable cars alongside other modes of transportation; the last cable tram closed down in 1923. Glasgow, Scotland, had an underground cable tramway system from 1896 to 1935. Paris operated a combination funicular and tramway from 1891 to 1935, providing service to the neighborhood of Belleville, which was built on a steep hill. Chicago had a cable tram system from 1882 to 1913; although the city is largely flat, it has severe winters, and the fact that the cable cars were little affected by weather was an advantage. Seattle, Washington, a city with extremely steep hills, operated a cable car system from 1888 to 1940, making it the last U.S. city other than San Francisco to keep a cable car system in operation.

Canals and Locks

A canal is an artificial waterway built with the purpose of moving ships, goods, and/or people. The term can refer to an inland waterway that allows for intra- or inter-urban transportation, such as those in Venice, Suzhou, and throughout the Low Countries. Alternatively, it may refer to an artificial channel that connects two previously unconnected bodies of water.

The first examples of canals date back to pre-modern times. Mesopotamian societies dug canals for irrigation and flood control as early as the 4th or 5th millennium B.C.E. Evidence of irrigation canals by Indus Valley, Nile Valley, Sumerian, and Inca civilizations is also available, and the existence of an extensive network of canals under the Roman Empire is confirmed by the remnants of stone aqueducts found throughout southern Europe. China's Grand Canal, which connects the cities of Beijing and Hangzhou, was commenced in the 5th century B.C.E. and completed in the 7th century C.E. and remains the world's longest artificial waterway. From the outset, the Grand Canal has been a significant artery of commerce in China and remains so to this day.

On a relatively small scale, canal traffic has been an integral component of overland goods transport in Asia and Europe for over a millennium. However, the Industrial Revolution was the impetus for the large-scale expansion of canals throughout Europe and North America in the late 18th and early 19th centuries. Though Europe's canal network was initially better formed, the westward expansion of the United States' population drove the development of numerous canals, such as the Erie Canal and the Chesapeake & Ohio, which in turn dramatically reduced commercial transport costs. This system of internal waterways led to the early growth and development of several major cities, including Buffalo and Chicago.

However, as railways began to undermine waterborne modes of overland transport, many canals began to lose their commercial utility. The most significant canals of today are those that play a key role in global shipping, such as Egypt's Suez Canal, which connects the Indian Ocean basin to the Atlantic basin, and the Panama Canal, which connects the Pacific Ocean to the Caribbean basin and ultimately the Atlantic. While the completion of major

transcontinental railroads and highways has all but replaced intracontinental ship traffic, globalization and an increasingly spatially fragmented division of labor ensure that intercontinental maritime traffic has increased greatly, particularly in the wake of the formation of the World Trade Organization (WTO) and the advent of containerization.

Locks

A lock is an enclosed chamber used for elevating or lowering boats within a waterway. The purpose of a lock is to allow the construction of canals where changes in elevation, tidal variation, or differences in elevation (for canals connecting two bodies of water), would otherwise preclude them. In the process of elevating a ship, a vessel moves inside the lock and once its gates are shut, the chamber fills with water, either by gravity-fed or pump-fed delivery mechanisms. The vessel rises along with the water level, and after it reaches the height of the adjacent chamber or waterway, lock gates on the opposite end open and it carries onward. In lowering ships, the process is the inverse: once the chamber gates are closed, water is slowly drained from the lock.

In terms of influencing global commerce, the size of the world's major locks often determines the dimensions of international shipping fleets. Notably, "Panamax," "Suezmax," and "Seawaymax" refer to the maximum length, beam, and draft of vessels able to enter the Panama Canal, Suez Canal, and Saint Lawrence Seaway, respectively.

Condition

Many large-scale ship canals serve a vital role in global commerce. However, with the sweeping changes that shifted intracontinental commercial traffic from waterborne vessels to road and rail transport, many of the world's small-scale canals have been relegated to historical artifacts. While these generally remain functional canals, their utility is often primarily in terms of recreational boating, historical preservation, and/or tourism, and many cities and regions have benefited from well-preserved canal systems. India's Kerala province, China's Guangxi province, and Russia's St. Petersburg are all major tourist destinations within their respective countries, all featuring unique historic canal systems. In terms of recreation, extensive "canal boating" takes place throughout Europe,

A series of small locks on the Rideau Canal in Ottawa, Canada, in 2011. The canal is the oldest in continuous use in North America. Small-scale historic canals and locks such as this often no longer serve the crucial role in transportation they once did.

and more recently, many master-planned communities have been built around artificial waterways in the U.S. state of Florida and the Australian state of Queensland.

Expansion Issues

Given the increasing size of seafaring vessels, many ports, sea lanes, and canals worldwide are being augmented to accommodate larger ships. Construction is under way in the port of Antwerp, Belgium, for example, to build the world's largest lock. The most significant of these projects under way is the Panama Canal expansion. Approved through public referendum in 2006, the \$5.25 billion project is financed by a suite of international banks and institutions and will significantly increase the canal's throughput. When completed, the largest ships passing through the Panama Canal will have a maximum capacity of 12,500 20-foot equivalent units (TEUs), nearly a

threefold increase from 4,400 TEUs in the preexpansion era. This expansion has led to the enhancement of numerous port facilities around the world in order to handle "New Panamax" ships.

The expansion of the Panama Canal is being carried out in response to growing demand for transcontinental shipments. Although the Suez Canal and transcontinental rail transport are currently its most significant competitors, the Colombian and Chinese governments have proposed a "dry canal" to connect the Caribbean and Pacific by rail, and several Central American governments have announced similar plans, though nothing major has materialized.

Car Sharing

The principle of car sharing is simple: individuals gain the benefits of private vehicle use without the costs and responsibilities of ownership. Instead of owning one or more vehicles, a household or business accesses a fleet of shared-use autos on an as-needed basis. Individuals gain access to vehicles by joining an organization that maintains a fleet of cars and light trucks in a network of locations. Vehicles are most frequently deployed from lots located in neighborhoods, at transit stations, or at businesses. Car sharing members typically pay for use through

hourly rates and subscription-access plans. Most car sharing operators manage their services with advanced technologies, which may include automated reservations, smart-card vehicle access, and real-time vehicle tracking.

Car sharing members have a variety of reasons for joining car sharing. Common reasons to join car sharing include the following:

- Environmental awareness
- Cost savings over owning a private vehicle
- Parking (maintaining vehicle access without the cost or difficulty of locating parking in an urban setting)
- Mobility insurance (access to a vehicle in case either a personal vehicle or commuting option is unavailable)
- Access to an additional vehicle (member who owns a primary vehicle and has a periodic need for a second or third vehicle but does not need to own an additional vehicle)
- Access to a vehicle on an as-needed basis (individuals selling a vehicle who retain a periodic need for a car and individuals without a vehicle who need periodic vehicle access)

Common goals among car sharing organizations include (1) reducing congestion and auto ownership; (2) providing cost savings since customers pay per use, sharing the costs of the vehicle lease, maintenance, repair, and insurance; (3) reducing emissions by lowering overall vehicle miles (kilometers) traveled and using clean fuel vehicles (for example, gasoline–electric hybrid cars); (4) facilitating more efficient land use (for example, car sharing reduces the number of parking spaces needed); and (5) increasing mobility options (for example, low-income market segment) and connectivity among transportation modes.

As car sharing has evolved, a number of niche markets have developed. A few of these include consumer car sharing, college/university car sharing, personal vehicle sharing (also known as P2P), and fleet-based services. In consumer car sharing, a company owns a fleet of vehicles to provide car sharing services for its members. College/university car sharing is very similar to consumer car sharing except that the car sharing operator's

goal is to provide vehicle access to university students (typically 18–25 years of age) and university staff and faculty. Personal vehicle sharing provides short-term access to privately owned vehicles. In personal vehicle sharing, private vehicle owners make their cars available for other drivers to rent. In fleet-based car sharing, government agencies and employers replace their own private fleets with car sharing services that can either be used exclusively as fleet cars or nonexclusively (fleet cars shared with ordinary car sharing users).

In addition to niche markets within car sharing, three different categories of operators provide car sharing services. These include automakers, rental brands, and car sharing brands. As of 2012, 10 automakers provided car sharing services or vehicles with factory-equipped telematics for car sharing. As of 2012, five rental-car brands were providing car sharing services worldwide. As of 2012, two automakers and three rental car brands were providing car sharing services in North America.

Types

In classic car sharing, a car sharing member joins an organization. Once approved, the car sharing organization typically sends its member an access mechanism (for example, smart card, key fob, etc.) used to access vehicles. Members typically go to the program's Web site to locate vehicles and select a model. Reservations can typically be made online or over the phone. When a member arrives for his/her reservation, the member unlocks the vehicle using the access mechanism.

Depending on the car sharing program, features may include open-ended bookings (that is, no fixed reservations), instant access (that is, no reservations), and one-way rentals (that is, vehicles can be returned to a different lot). Pricing also varies among programs. Some car sharing programs charge users based on length of time a vehicle is in use, distance-based fees based on cost per mile/kilometer, or a combination such as varying amounts of free mileage per an hour of use.

Shared-use services expanded into a new market segment, known as personal vehicle sharing (P2P), through the use of privately owned vehicles. In this model, personal vehicle sharing companies broker transactions among vehicle owners and renters by providing the organizational resources to facilitate these transactions (that is, online platform,

customer support, auto insurance, and technology). A few of the operators providing this type of service offer a hybrid car sharing service in which individuals have access to both private autos and a fleet of that operator's own vehicles. Additionally, new technologies are emerging that enable direct exchanges between individuals via the Internet (known as the "P2P marketplace").

Historical Overview

Car sharing became popularized in Europe in the mid- to late 1980s. Car sharing expanded to North America and Asia in the 1990s. Car sharing operations launched in Australia and South America in 2003 and 2009, respectively. In October 2012, there were nearly 1.8 million car sharing members worldwide, sharing approximately 43,500 vehicles. Of this, Europe and North America accounted for 39 percent and 51 percent of the worldwide membership, respectively. Asia accounted for 9 percent of the worldwide membership. Australia and South America collectively accounted for approximately 1 percent of the worldwide membership. As car sharing has evolved, phases of market development have become apparent, particularly in North America.

Phases of Car Sharing

In North America, car sharing evolution has progressed through three phases: initial entry and market experimentation (1994 to mid-2002), growth and market diversification (mid-2002 to late 2007), and commercial mainstreaming (late 2007 to present).

The first car sharing operators in North America modeled their operations after successful car sharing efforts in Europe during the late 1980s and early 1990s, focusing on neighborhood car sharing. The earliest Canadian operator, Auto-Com (now Communauto) was established in 1994. In the United States, CarSharing Portland became the first organization in 1998.

Initially, four major business models emerged: for-profit, nonprofit, cooperative, and university research programs. This early phase marked a wave of new entrants, technological development from manual operations to phone and Internet reservations, high-cost and difficulty locating insurance, and the first industry merger between Flexcar and CarSharing Portland in June 2001.

The second phase of carsharing reflected growing memberships, fleets, market diversification (for example, business car sharing, government fleets, and residential partnerships), capital investment, and multinational market entry. (Zipcar launched international operations in 2006.) By 2003, a number of car sharing organizations were operating in multiple regions, leading to new economies of scale and greater market penetration. Also in 2003, independent car sharing operators, including cooperatives, nonprofits, and for-profit organizations, formed an informal association.

Since 2003, interoperator collaboration increased, including the North American Code of Ethics for the Carsharing Industry (ratified by 20 operators, the majority nonprofit, in 2007), public policy collaboration, roaming memberships (members of one organization can submit their driving records to another organization to access their service), and technology development. The second phase was also marked by higher member-to-vehicle ratios, particularly in the United States, as operators sought to increase vehicle use and profitability to attract investors.

At the time, the merger of North America's two largest operators (Zipcar and Flexcar) marked the beginning of the commercial mainstreaming phase. Program mergers, the expansion of multinational operations, and market specialization have been notable characteristics of this phase. Some of these niche markets include the development of personal vehicle sharing, one-way car sharing, and the entry and expansion of both automakers and rental car brands into the car sharing marketplace.

In North America, U-Haul launched its car sharing service in May 2007, followed by Enterprise in February 2008, and Hertz in December 2008. Similarly, Daimler AG's car2go launched North American operations in May 2010, followed by BMW's DriveNow in June 2012. Other characteristics of this phase include ongoing market growth, interoperator collaboration, technological development, and a greater emphasis on public policy.

Impacts of Car Sharing

A number of social and environmental benefits are commonly associated with car sharing. The impact of car sharing can be categorized into transportation, environmental, land use, and social effects. A major impact of car sharing on the transportation system is a reduction in vehicle ownership. A

reduction in vehicle ownership, in turn, is likely to result in fewer vehicle miles or kilometers traveled (VMT/VKT), reduced traffic congestion and parking demand, and an increase in the use of public transportation and other transport modes (such as biking and walking) in lieu of car travel.

Estimates differ substantially between members who gave up vehicles after joining a car sharing program and those who gained vehicle access through car sharing. Car sharing also induces lower VMT/VKT by emphasizing variable driving costs, such as per-hour or mileage charges. Furthermore, reduced vehicle ownership and VMT/VKT lower greenhouse gas (GHG) emissions, as trips are shifted to transit, biking, and walking.

In addition, many car sharing organizations include low-emission vehicles, such as gasoline-electric hybrid cars, in their fleets. Car sharing members also report a higher degree of environmental awareness after joining a car sharing program. Finally, car sharing also shows evidence of beneficial social impact. Households can gain or maintain vehicle access without bearing the full costs of car ownership. Depending on location and organization, the maximum annual mileage up to which car sharing is more cost-effective than owning or leasing a personal vehicle lies between 6,214 to 10,000 miles. Low-income households and college students can also benefit from participating in car sharing.

Public Policy Considerations

A number of supportive and unsupportive policies have been implemented that impact car sharing. Generally, the majority of these public policies can be classified into five categories: (1) developer and zoning regulations, (2) fleet reduction, (3) parking policies, (4) risk-sharing, and (5) taxation.

In North America, policies have been developed to encourage car sharing in new developments. These policies include parking reduction (that is, downgrading the required number of spaces in a new development), parking substitution (that is, substituting general use parking for car sharing stalls, and allowing greater floor-to-area ratios (that is, developers can build more densely on-site).

A key component of fleet reduction policies is replacing a business or public agency's motor pool with car sharing services or supplementing peak demand of their motor pool with car sharing services (allowing for the retirement of underutilized

A car sharing vehicle in a dedicated parking space in Marburg, Germany, in 2009. Car sharing emerged in Europe in the 1980s. By 2012, Europe accounted for 39 percent of car sharing, North America for 51 percent, and Asia for 9 percent.

vehicles). The greatest number of public policies typically involve car sharing parking. These policies include (1) provision for on-street parking, (2) provisions for off-street parking, (3) exemption from parking limits, (4) creation of car sharing parking zones, (5) free or reduced cost for car sharing stalls, (6) free or reduced-cost parking permits, (7) universal parking permits (that is, car sharing vehicles can be returned to any on-street location), (8) formalized processes for assigning on-street parking spaces, and (9) use of parking meter revenue to subsidize car sharing.

Three common risk-sharing partners include local governments, universities, and property management firms. Methods of risk-sharing include (1) partnering with organizations to purchase membership blocks and/or guarantee vehicle use, (2) vehicle subsidies, and (3) the "subtraction model" whereby a car sharing operator values the monthly

cost of vehicle placement and subtracts monthly revenue from that collected value and bills the shortfall to the risk partner.

Common policies on taxation include local and state sales tax credits, exemptions from car rental taxes, tax credits to employers and property managers providing car sharing services, and the levying of special-use and/or sales taxes on car sharing services.

Carbon Dioxide Emissions

Few environmental issues facing short- and long-term transportation systems planners ignite more heated debate or more apocalyptic rhetoric than the role of steadily increasing carbon dioxide emissions in global temperature change. So-called greenhouse gases—naturally occurring atmospheric gases, among them methane, nitrous oxide, and most prominently carbon dioxide—act to absorb dangerously high levels of solar radiation, trapping it near Earth's surface rather than allowing it to escape harmlessly into the atmosphere. In turn, that contributes dramatically, according to a growing body of hard scientific data, to the phenomena of global warming and ultimately long-term climate change.

Carbon dioxide accounts for more than 80 percent of all greenhouse gases, and the increases in its production from human activity, most prominently the burning of fossil fuel to move virtually all types of vehicles, has raised significant challenges for those who design transportation systems, vehicle engines, and transportation routes. Concerted action is difficult as the problems are global. The scope of the transportation system in the United States alone is staggering: more than 3.9 million miles of paved roads; flights departing virtually every minute from more than 5,000 airports; 3.7 trillion tons of goods shipped domestically each year by truck, plane, train, and ship; one in eight jobs nationally tied to the transportation system. On any given day, close to 30 million children alone rely on buses for transportation to and from school.

Carbon dioxide itself is part of the natural activity of the carbon cycle; it is manufactured in a range of natural processes including photosynthesis, volcanic eruptions, and even breathing. Left to its own devices, nature largely balances out this carbon dioxide output, removing the gas most notably through its interaction with plants and trees that act as filters, and for the nearly 9,000 years of human presence on Earth that rhythm was largely maintained. However, in the two centuries of the Industrial Revolution, the output of carbon dioxide from unchecked human activity has significantly impacted the ability to control the emission levels.

Climate Change

Because research into climate change has become quite prolific over the last quarter century (thousands of reports issued annually, often with conflicting data) and because the argument of global warming has become a polarizing political issue (vocal arguments from the political right cast doubt on such scientific data and dismiss global warming itself as alarmist, antibusiness hand-wringing), it has been difficult to coalesce the argument for those who advocate stricter controls and better long-term transportation system planning not just within the United States (although the United States is second only to China in carbon dioxide emissions) but globally as well.

Although environmental researchers point to a variety of destructive human activities since the advent of the Industrial Revolution that have contributed to the problem—most prominently wide-scale indiscriminate deforestation and the combustion of fossil fuel to power more and more massive electrical plants—burning fossil fuels to maintain the global transportation system, including cars, planes, boats, and trains, is responsible for nearly a third of the total carbon dioxide emissions. More alarming, data indicates that in just 20 years, from 1990 to 2010, these carbon dioxide emissions have spiked more than 10 percent, a measure, advocates of long-term strategic transportation policy planning claim, of the evident failure of timid legislation intended to address energy consumption within the nation's transportation system.

Time for effective action is rapidly shrinking. In 2012, carbon dioxide emissions rose globally a record 1.4 percent, which scientists fear could set global temperature increases dangerously ahead of alarming predictions made barely a decade ago. Data that measures the cumulative volume of carbon dioxide in the atmosphere indicates that just two centuries ago carbon dioxide in the atmosphere measured less than 280 parts per million (ppm); in 2013 that number soared past 400 ppm for the first time in human history, a level long held to be a wake-up call for governments and businesses, underscoring the failure of public and private strategic transportation planning.

Reduction

The simplest way to address the problem with carbon dioxide emissions, of course, is collective

efforts to reduce the consumption of fossil fuels. It is not an exaggeration, scientists have argued, that every car trip, every cross-oceanic transport, every flight from crop dusters to jets, every turn around the lake in a powerboat ultimately registers in the amounts of carbon dioxide in the atmosphere.

Some progress has been made. The steadily escalating price of gasoline since 2000 (nearly doubling in price) has acted to depress the volume of driving as drivers conserve trips; share rides; pursue walking/cycling options; slow down; buy smaller, more fuel-efficient vehicles; and reorganize work schedules to allow work-at-home options or opt to live closer to work sites. But Department of the Interior data indicates that more than two-thirds of the vehicular transport in the United States alone is industrial, not personal: the vast transportation system makes accessible markets and materials to industries and such transportation needs cannot easily be downsized without dramatically impacting other sectors of the economy.

If regulating vehicle use poses too formidable a challenge, environmental advocates champion immediate and significant government and industry support for developing more fuel efficient vehicles that would use cleaner, renewable energy, such as hybrid models or electric cars that are currently too expensive and too inefficient for wide market acceptance. But economic uncertainties often drive increases in vehicle use; environmental researchers point to increasing distances workers must travel to accommodate job responsibilities; the relocating of families to follow economic opportunities; and car owners holding on longer to older, less fuel efficient vehicles, all of which, social and political scientists argue, points to the necessity of immediate local and state government long-term commitment to revitalizing the nation's crumbling infrastructure, giving drivers who must depend on their vehicles access to the quickest, most efficient routes. In addition, local governments could fund newer mass transit systems in high population centers.

Broader solutions involving other transportation systems that have been recommended by scientists have included redesigning the network of global shipping lines, drawing smarter, more direct routes despite political acrimony between and among nation states; revamping often antiquated railroad lines; developing lighter airplanes and phasing out older, heavier models; and maintaining air traffic

efficiency to minimize wait times on runways. However, environmental advocates largely agree that the most effective long-term strategy to control carbon dioxide emissions is to promote a radical (and across the board) change in vehicular driving habits.

Carbon Monoxide Emissions

Carbon monoxide (CO) is an invisible and odorless gas that is toxic to humans in high concentrations and at long exposure durations. Carbon monoxide is produced naturally through photochemical reactions in the troposphere (lower atmosphere), and often produced as a by-product of incomplete fossil fuel combustion, such as burning coal to produce electricity or powering an internal combustion engine with gas, diesel, or natural gas fuel. In the latter case, CO comes from the unburned vehicle fuel released after combustion in engine cylinders. In the United States, this process is responsible for most CO emissions; the U.S. Environmental Protection Agency (EPA) estimates that

motorized vehicles produce around 86 percent of all CO nationwide. Of this total, on-road vehicles are responsible for 65 percent, nearly 90 percent coming from light-duty vehicles.

Regulation

Effective emissions regulation in developed countries has mostly eliminated the dangers of carbon monoxide emissions. Vehicle emissions control systems (for example, catalytic converters and electronic fuel injection systems) have evolved to meet increasingly tight regulations placed on manufacturers, beginning in the 1970s with the passing of the federal Clean Air Act. Between 1980 and 2010, average U.S. urban CO concentrations fell 82 percent, and levels now lie well below the National Ambient Air Quality Standards (NAAQS).

Carbon monoxide is considered a "primary" pollutant—one that may cause direct health impacts from prolonged or high-concentration exposure. The World Health Organization (WHO) suggests that only high concentrations of CO are likely to affect human health, when hypoxia (a fatal lack of oxygen) begins to take effect. WHO suggests limiting exposure to no more than 90 parts per million (ppm) molecules of air for 15 minutes, 50 ppm for 30 minutes, 25 ppm for one hour, or 10 ppm for eight hours. In the United States, the Occupational Safety and Health Administration (OSHA) prohibits its exposure to concentrations greater than an average of 50 ppm during an 8-hour time workday.

In ambient (outside) air, the NAAQS specify that CO concentrations, averaged over an eight-hour period, must not exceed 9 ppm, or 35 ppm for any one-hour average. If a region surpasses either of these standards more than once (for each measure), it is considered out of compliance and must take action to reduce its CO emissions. These standards for carbon monoxide were first established in 1971 to protect both public health and welfare, but a 1985 review determined that public welfare (that is, adverse effects to ecosystems and the natural environment) impacts of CO were insignificant at existing ambient-air levels, so these were dropped from the standards. The EPA reviewed these standards once again in 1994 and made no changes. As of 2013, these standards remain in place and measurements of ambient air at all U.S. locations are in compliance.

As a means of meeting NAAQS, the EPA sets threshold emissions rates for CO and other

pollutants from individual vehicles, a key source of urban air pollution. The latest EPA standards (as of 2013) for all light- and medium-duty passenger vehicles require emissions no higher than 3.4 grams per mile (g/mi), for vehicles at or below 50,000 miles of total use. Vehicles between 50,000 and 120,000 miles of use are allowed CO emissions rates up to 4.2 g/mi. European Union standards for carbon monoxide emissions are now stricter than those in the United States. The latest EU standards (Euro 5) allow no more than 1 gram per kilometer (g/km) (1.6 g/mi) for gasoline passenger vehicles and no more than 0.5 g/km (0.8 g/mi) for similar diesel vehicles. The next Euro regulation phase, Euro 6, will maintain these CO standards.

Localized Concentrations

Although ambient carbon monoxide emissions and levels are no longer a key concern in the United States, localized CO emissions remain a potential hazard. Certain microenvironments (like parking garages, at gas stations, and inside queued vehicles) regularly experience higher CO concentrations, and some poorly ventilated and partially enclosed areas (like underground or multistory parking structures) may trap CO, creating pockets of very high concentrations, particularly in very cold climates, during cold starts (when fuel ratios are purposefully rich).

CO levels as high as 100 ppm have been recorded for extended periods in some urban garages and parking complexes, which becomes very hazardous, even when experienced for a matter of only minutes. Running an internal combustion engine in an enclosed space (for example, a vehicle idling in a garage) can cause suddenly harmful and even fatal spikes in carbon monoxide concentration. The Centers for Disease Control and Prevention (CDC) found that it took only seven minutes for a small 5-horsepower gasoline engine in a 10,000 cu. ft room to raise ambient CO concentrations to as high as 1,200 ppm.

Smog

While ambient concentrations of CO tend to pose threats only to human (and animal) health, the gas can combine with other pollutants to form ground-level ozone, or “smog,” harming health and the environment. Carbon monoxide combines with hydroxyl radicals to produce nitrogen

dioxide from a series of intermediate reactions. Nitrogen dioxide produces ground-level ozone (smog) through interactions with solar radiation. Smog can cause eye, nose, and throat irritations in the short term and damage lung tissue, leading to chronic lung disease in the long term. Smog also reduces visibility and can damage agricultural crops and man-made surfaces.

As of 2013, many U.S. regions exceeded the NAAQS eight-hour average concentration limits for ground-level ozone (0.075 ppm). Though carbon monoxide is not the primary contributor to ozone formation, it can provide an additional catalyst for smog formation, which remains a significant concern in the United States and around the world. For example, Mexico City regularly experiences very high levels of ground-level ozone, spurred partially by high CO concentrations, and China’s urbanization has created dramatic smog episodes, readily apparent through reduced visibility.

Conclusion

As demonstrated by regulations and vehicle design trends in the United States and Europe, the public health impact of CO emissions can be greatly reduced through emissions regulations and more efficient vehicles. However, even with today’s most advanced engines, carbon monoxide emissions are inherent to gasoline- and diesel-fueled vehicles. Electric-drive vehicles provide an option to reducing CO tailpipe emissions completely, but one must ensure upstream CO emissions from power plants remain low.

Carbon monoxide emissions from automobiles have largely disappeared as a direct health threat in most ambient-air settings, but urban growth, rising motorization, and certain microenvironments can contribute to dangerous concentrations of CO, along with other harmful pollutants. Carbon monoxide emissions now represent a mostly dormant threat to ambient air quality but may cause isolated and local health episodes and should continue being monitored to ensure clean air remains the norm.

Carpool Programs, Ridesharing and

Ridesharing has long been viewed as an approach to address problems of traffic congestion, carbon emissions, and fossil fuel dependence. The objective of ridesharing is to fill empty vehicle seats by matching riders with drivers going in a similar direction, employing vehicle occupancy potential to reduce the number of vehicles on the roadways. Ridesharing is largely realized through carpooling and vanpooling, the grouping of travelers in a private automobile or van, respectively. Ridesharing also includes more unique forms, such as casual carpooling (also known as "slugging"). North American ridesharing has a 70-year history, which began with carpooling programs during World War II and has evolved through five phases until today. Ridesharing's modal share has declined since the 1970s, when 20.4 percent of American workers commuted to work by carpool. Despite this drop, it remains the second-largest travel mode in the United States, at 10.2 percent as of 2011.

In traditional definitions, ridesharing differs from for-profit commercial transportation (for example, taxicabs, limousines) in its financial motivation. When a ridesharing payment is collected, it partially covers the driver's cost; it is not intended to result in a financial gain. Moreover, the driver has a common origin and/or destination with the passengers.

Because ridesharing reduces the number of automobiles needed by travelers, it claims numerous societal benefits, including reduced emissions, traffic congestion, and parking infrastructure demand. However, the magnitude of such benefits is unclear. On an individual level, the benefits are more tangible. Carpool and vanpool participants experience cost savings due to shared travel costs, travel-time savings through the use of high occupancy vehicle (HOV) lanes, and reduced commute stress, particularly for those with longer commute distances. In addition, they often have access to preferential parking and additional incentives.

Despite its many benefits, there are numerous behavioral barriers to increased ridesharing use. Individuals often see the attractiveness of carpooling but are disinclined to sacrifice the flexibility and convenience of the private automobile. Moreover, psychological factors, such as the desire for personal

space and time and an aversion to social situations, can impact ridesharing adoption. Personal security is also a concern when sharing a ride with strangers, although this is a perceived risk. Carpool programs over the years have attempted to address these barriers using incentives and emerging technology.

History

Ridesharing's evolution has a 70-year history in North America and can be categorized into five key phases: (1) World War II car-sharing clubs (1942–45), (2) major responses to energy crises (late 1960s–80), (3) early organized ridesharing schemes (1980–97), (4) reliable ridesharing systems (1999–2004), and (5) technology-enabled ridematching (2004–present).

Ridesharing began as a policy mechanism during World War II, encouraged by the U.S. federal government as a way to reduce the consumption of steel, rubber, and petroleum needed for the war effort. A 1942 U.S. government regulation required that ridesharing arrangements to workplaces be made when no other alternative transportation means were available. The U.S. Office of Civilian Defense created a ridesharing program called the Car Sharing Club Exchange and Self-Dispatching System, which matched riders and drivers through a bulletin board at work.

Following the war, the need for ridesharing became less apparent. However, it reemerged in the late 1960s and early 1970s at major employment sites. Large-scale employers, challenged with managing congestion and office parking supply, turned to commuter ridematching programs. These programs were simple and successful—each company collected employee data, hand-matched those who were neighbors, and distributed personalized matches. The 1973 Arab oil embargo shifted ridesharing's focus from constrained parking supply concerns to energy conservation. Employer-sponsored commuter ridematching programs caught the attention of U.S. federal agencies as an aggressive tool to achieve energy conservation goals. The Federal Highway Administration (FHWA) began cataloging successful employer ridematching programs to publish guidebooks on carpooling and vanpooling. Additionally, the 1974 Emergency Highway Energy Conservation Act provided federal highway funds for over 100 carpool demonstration programs across the United States through 1977.

As a result, carpool and vanpool programs have become a common transportation demand management (TDM) strategy, encouraged simultaneously by public agencies and major trip generators (for example, employers, universities) to reduce congestion and parking demand. Since the 1970s, other policy mechanisms, including HOV lanes, preferential parking for carpools and vanpools, and park-and-ride facilities have been developed to encourage ridesharing.

As energy conservation efforts waned in the 1980s and 1990s, TDM policies shifted focus to alleviating suburban office park congestion and air quality issues. Public agencies implemented mandatory employer-based trip reduction (EBTR) programs; the largest, known as Regulation XV, affected over 2.3 million employees in southern California. By the early 1990s, however, unrealized goals and growing opposition ended most EBTR programs. Advances in computerized ridematching during this period also marked a move toward more dynamic ridesharing applications in the form of telephone- and Internet-based ridematching programs. Notable pilot programs include Bellevue Smart Traveler, Los Angeles Smart Traveler, and Rideshare Express in Sacramento. These programs were deemed unsuccessful due to low use. Ridesharing's growth was limited during this phase due to lower gasoline prices coupled with ridesharing's lack of flexibility, safety concerns, and ride-matching challenges.

With most dynamic ridematching applications of the 1980s and 1990s failing to overcome the “critical mass” barrier (that is, providing enough users to consistently create a successful instant ridematch), most North American carpooling programs between 1999 and 2004 focused on systems to encourage ridesharing among commuters who had the most reliable trip schedules. Since 1999, private software companies began developing ridematching “platforms,” providing their suite of services to clients for a monthly fee. Carpools formed through online ridematching tended to be more static and inflexible and required prearrangement. Though it was easier to find ridematches in a larger online database, these carpools still suffered from the same drawbacks as traditional carpools, namely, regular commuters lost the flexibility that private auto travel offered. As housing and employment centers became more dispersed, offering less

incentive to rideshare, online ridematching had difficulty attracting more users than the employer-sponsored commuter ridematching programs of the late 1960s. Thus, online ridematching programs seemed to be best suited for commuters with similar, consistent schedules.

From 2004 to the present, a new generation of ridematching platforms has been developed for regions and employers to use with significant growth and overall success. Partnerships between ridematching software companies and their large-scale clients take advantage of existing common destinations and a large number of potential members. These firms sell their ridematching software “platforms” to public agencies and employers, which are sometimes used as stand-alone Web sites for each group. While this partnership strategy has gained more users than previous ridesharing phases, it is still most suited for commuters with regular schedules. Today, there are over 600 ridematching programs in North America, most of which use online, automated ridematching.

Many public agencies and employers also manage carpooling programs that provide members with incentives for “green trips.” Members are rewarded with points when they carpool, vanpool, take public transit, bike, walk, or telecommute for both work and personal trips. These points can be used for restaurant coupons, shopping discounts, and attraction tickets from sponsoring businesses.

Another major development in this phase has been real-time ridematching, made possible through social networking services (for example, Facebook) and mobile/smartphone technology. Real-time ridematching services match drivers and passengers through a smartphone “app” minutes before the trip is to take place, addressing the inflexibility of prearranged carpooling. A driver has the app open on a GPS-enabled smartphone. Meanwhile, a potential rider requests a ride through the app and is shown nearby drivers going a similar direction. Once the rider requests the ride, the driver is notified, confirms the ridematch, and drives to pick up the rider. Trips made are typically short, intracity trips. The rider pays a suggested donation, automatically calculated through the app, by authorizing a credit card transaction through the ridematching service. The app companies take a commission of that monetary transaction. After the trip, both the driver and rider rate their experience with the other party.

The rise of mobile technology and social networking to enable real-time ridematching has blurred the distinction between traditional ridesharing and commercial transportation (for example, taxis). Because of this, there remains controversy between new real-time ridematching companies and the commercial transportation industry regarding regulation, competition, innovation, and public safety. Nevertheless, real-time ridematching companies continue to expand to major cities across the United States, including San Francisco, Los Angeles, Seattle, Chicago, and Washington, D.C.

Ridesharing’s Future

Evolving technology has played a part in carpooling programs through each phase of ridesharing and will play a critical role in ridesharing’s future. Perhaps its greatest contribution will be to help overcome the critical mass barrier, which has limited the potential of this mode in the past. Interoperability among numerous ridematching databases, or a “ridematch aggregator,” could achieve a notable step in this direction.

Another area that could foster growth is multimodal integration—the seamless connection of ridesharing with other transportation modes, such as public transit and car sharing (or short-term auto access). A significant challenge to future integration and interoperability, however, is the establishment of institutions to facilitate collaboration among public agencies and private companies to support this.

Finally, supportive policies in the United States and Canada are essential to facilitating ridesharing growth over the next decade. A range of TDM policy strategies could integrate and promote ridesharing, such as free or reduced-price access to high occupancy toll (HOT) lanes, parking cash-out (that is, employees can opt out of a parking space and receive compensation from their employer who leases/owns the space), and pretax commuter incentives (that is, commuters are not taxed on ridesharing expenses). Ultimately, effective policies must demonstrate to employers and travelers that ridesharing and carpooling programs will positively impact their lives through tangible incentives.

Carpooling

Carpooling occurs when two or more people occupy the same vehicle and travel between the same or similar origins and destinations. Carpools may consist of people of the same household (called intrahousehold carpools or fampools) or may consist of friends, coworkers, neighbors, or others who reside outside the household (interhousehold carpools). Carpool arrangements may occur relative to a specific trip and remain more informal in nature or individuals may make formal arrangements (including financial) to share rides on a regular basis. Much of the research on carpool behavior has focused on formal carpool arrangements for the work commute, although newer research has extended the focus to fampools and to understanding the characteristics of carpool trips for other purposes.

Although carpooling was encouraged by governments to conserve gasoline and rubber for military use during World War II, little is known about carpooling prior to the late 1970s, when carpooling was included as a separate mode choice option in the 1977 Nationwide Personal Transportation Survey. The oil crises of 1973 and 1977 brought about an interest in finding ways to decrease American and European dependence upon foreign oil. Since transportation accounts for the largest proportion of oil use, one of the best ways to decrease dependence was to find ways to reduce transportation fuel use. In addition, increased fuel costs led to growth in carpool use from the mid-1970s through the mid-1980s. This interest in learning new ways to lessen gasoline use led to the first waves of research on carpooling behaviors in the late 1970s and 1980s. This early research focused on the attitudes and preferences for different work commute modes and ways in which public and private policies could influence changes in transportation mode choice from single occupancy vehicles (SOV) to public transportation or carpooling.

The nascent carpool research used statistical models similar to those used for analyses of consumer behavior. Thus, economic models estimating elasticity of demand for carpooling (usually measured relative to the cost of gasoline) or psychological-related models measuring individual preferences for transportation mode choices and various incentives for switching to carpooling were used. This early research was used to measure the effectiveness of various public transportation management programs, such as developing high occupancy vehicle (HOV) lanes, monetary incentives, and workplace ridesharing programs. Shares of workers carpooling declined during the 1980s despite these efforts and subsequently research about carpooling waned.

Socioeconomic and Other Differences

While early research on carpool behavior sought to understand how individuals choose carpool or public transportation over other modes, changes in the racial/ethnic characteristics of the population has expanded the research focus to seek a better understanding about who commutes and why. For instance, Hispanics are more likely to carpool than any other racial/ethnic group. The reasons for higher carpool shares for Hispanics are varied.

A high occupancy vehicle (HOV) lane for “carpools only” on a highway between Los Angeles and San Diego, California, in 2009. In the 1970s, 20.4 percent of American workers commuted by carpool. By 2011, that number had fallen to 10.2 percent.

Hispanic workers may have higher commuting cost burdens (as a result of lower earnings relative to the costs of fuel, maintenance, parking, and distance traveled). In addition, Hispanics have larger average household sizes than other racial/ethnic groups, and as a result, Hispanic carpool arrangements are more likely to consist of family members than any other group. Finally, lower licensure rates of Hispanics, and particularly Hispanic women, leads to the formation of carpools where public transportation is not available or where it may be difficult to access and use.

Of special interest to researchers are the ways in which immigrants use carpools for work or other trips and how the use of carpool arrangements among immigrants changes with time in the United States. Carpooling may be thought of as a form of social capital—a way for new immigrants to use the assistance of others to navigate new environs. Language, cultural, educational, and legal barriers may keep immigrants from driving on their own so they must depend on other

arrangements, such as carpools, to get to work or other activities. With time in the United States, these immigrants may become more like the native born and carpool less. While some of these immigrant carpool arrangements are the same as carpool arrangements of nonimmigrants, that is, informal arrangements between family, friends, neighbors, or coworkers, researchers have discovered through qualitative research ways in which some immigrant carpool arrangements may look more like taxi services. In these instances, other immigrants operate often unlicensed vans or small buses, charging flat fees to transport fellow immigrants to work or other places.

Alternative Carpool Arrangements

Increases in gas costs in the first decade of the 21st century and continued interest in environmental issues led to renewed interest in research on alternative forms of transportation. In many ways, this new research has returned to the same issues of the 1970s and early 1980s, trying to understand and evaluate the effectiveness of public policies designed to incentivize carpooling or create disincentives to driving alone.

This research has also expanded into uncovering the ways in which people arrange carpools. For instance, one phenomenon studied has been the development of a system whereby individuals wait near an entrance to a high occupancy vehicle (HOV) lane to be picked up by drivers wishing to avoid congestion in non-HOV lanes. These informal carpool arrangements are called slugging. New research has also investigated the effectiveness of dynamic ridesharing programs that use the Internet and smartphones to arrange regular or occasional carpools via online carpool arrangement services.

Carpooling, Casual

In traditional carpooling, employees from the same company or individuals who work in close proximity prearrange travel together to work to save money and possibly take advantage of benefits such as carpool parking or the use of high occupancy vehicle (HOV) lanes to save time. However, carpooling is infrequent, with rates in the United States at just over 10 percent according to the U.S. Census Bureau's 2005–07 American Community Survey. Many who have the opportunity to carpool but choose not to cite the inflexibility and inconvenience in being tied to another person's schedule or that they themselves do not have regular work schedules.

Casual carpooling, colloquially dubbed "slugging," brings anonymous strangers together on the fly to travel together to save time and money. In this system, lines of riders congregate at designated locations. Drivers pull alongside the line and shout their destination or have a sign affixed to their vehicle. The first two commuters in the queue also traveling to that location enter the car

and, with three passengers, the vehicle can enter the HOV lanes, which can reduce the commute time by 30 percent. While some metropolitan regions across the world have fledgling casual carpooling cultures, slugging is well developed in the Washington, D.C., metro area, the San Francisco Bay region, and Houston, Texas.

Origin

Slugging originated in the Washington, D.C., metro area during the mid-1970s. At that time, commuters were concerned about gas prices and availability due to OPEC (Organization of the Petroleum Exporting Countries) oil embargoes. Concurrently, Northern Virginia's I-95/I-395 (Shirley Highway) opened the first freeway HOV lane, requiring at least three passengers to gain admittance to this coveted stretch of roadway operating between Prince William County in Virginia and Arlington Street near the Pentagon. Motorists who wanted to take advantage of the quicker HOV lane would drive up to bus lanes and solicit riders. Bus drivers, who were trained to spot "slugs," or counterfeit coins, it is said, began calling the commuters waiting in the bus line slugs since they were using the bus stops not for public transit but for a ride in a private vehicle.

Rules of Etiquette

While each slugging region has particular norms, over the past three and a half decades of casual carpooling, clear rules of etiquette have emerged for participants. Drivers are expected to drive safely and responsibly, have working seat belts, and present relatively clean vehicles. For their part, passengers are expected to refrain from eating and using their cell phones. They are typically quiet unless talked to by the driver. Reporters and researchers who have participated in casual carpooling note that some rides are silent, but others turn into enjoyable roundtables with lengthy discussions, and one man indicated he and his wife had met through slugging. The drivers can have quiet music or radio talk stations playing, as long as they are not overtly religious or political, and the passenger does not ask the driver to change the music or station, nor does the passenger make requests to alter the climate control settings. Historically, no money has changed hands between driver and passenger. In 2010, however, the Bay Area Toll Authority began charging cars in the carpool lanes a minimal fee,

currently at \$2.50, to cross bridges in the San Francisco area. The necessity to discuss financial transactions in the casual carpooling community ignited a firestorm of debate, with some passengers adamantly against contributing to the toll, some willing to pay whatever the driver requested, and some always contributing a dollar.

Since the toll's introduction, a consensus has emerged that passengers pay \$1 toward the toll, though the fiery debate reveals the dynamic social contract underlying casual carpooling. However, without these social norms, passengers would likely not feel comfortable entering a stranger's car for a lengthy commute. The rules of etiquette provide a shared sense of expectations that undergird a thriving slugging community.

Structural Requirements

Clear and widely accepted rules of etiquette provide the social context needed for casual carpooling. However, successful casual carpooling areas also share certain structural requirements. Researchers conducting the Casual Carpooling Scan report observed that slugging flourishes in areas with barrier-separated and reversible HOV lanes. Typically, HOV-3 lanes, those that require at least three passengers, see more slugging than regions with HOV-2 lanes. Park and ride lots, particularly ones that provide direct access to HOV lanes, spur slugging as well. The researchers also observed that the slugging communities typically have high travel demand, at both the origin point and the destination. At the destination, typically parking is rare or, when available, prohibitively expensive. In the cases of Washington, D.C., and San Francisco, a high proportion of workers travel to a tight geographical area. Additionally, passengers prefer a public transportation backup in case they are unable to secure a ride in a private vehicle. Most slugs want to be able to see bus lines from the slug lines so that they can make a choice to use public transit or wait for the next privately owned car.

Usage

The number of participants taking advantage of casual carpooling can be difficult to measure, although a handful of studies have been conducted on this carpooling subculture. The most prevalent research techniques involve participant-observation studies, interviews, and surveys. In May 2011,

511 Rideshare conducted observation studies and distributed surveys in the Bay Area at 13 East Bay slugging lines and one line in San Francisco. Based on their observations and the results of the survey, 511 Rideshare estimated a weekday daily participant rate of 6,100, a decrease of 9 percent since 2010. Survey respondents said they used casual carpooling to save time and money. Those who did not frequently use casual carpooling explained that they found it too onerous and confusing or that they did not have public transportation options for their commute home. Others cited the awkwardness or confusion brought on by the injection of money in the system when the Bay Bridge Toll Authority required the new toll on vehicles traveling in car-pool lanes.

The Washington, D.C., area claims about 10,000 participants in casual carpooling each weekday, perhaps because of the availability of information or because most slugs work for the federal government and have similar and consistent work schedules. Under the direction of Mark Ojah and Mark Burris, researchers observed casual carpoolers at select slug lines in June 2003 to estimate participation rates. Their observations indicated approximately 500 participants per day at the three slugging sites surveyed.

Since their research, one of the highways with slug lines was renovated. In addition to adding lanes to the highway, the HOV lanes were transformed into high occupancy transit (HOT) lanes, which allow single occupancy vehicles to use the lanes for a toll. Since the renovations, the number of casual carpoolers in the Houston area has decreased substantially. Among slugs, the Scan researchers noted diversity in terms of gender, ethnicity, socioeconomic status, and employment class.

Environmental Benefits

Most casual carpoolers join the ranks of slugging not because of the environmental benefits but because of the time and financial savings that comes from ridesharing. However, the practice does have environmental benefits. According to the Environmental Protection Agency, 27 percent of U.S. greenhouse gas emissions can be attributed to transportation. Passenger vehicles compose almost 60 percent of the sources of greenhouse gases. Automobiles and highway vehicles utilized roughly half of all the petroleum-based energy

used in transportation. At the same time, 75 percent of highway seats are empty, according to Raj Kapoor of the Mayfield Fund. When those empty seats are filled, fewer private vehicles are on the highway system, which amounts to 6 million fewer gallons of gasoline used annually, thereby reducing greenhouse gas emissions from commuting. Additionally, fewer private vehicles translate into a reduced amount of land exploited for roads and parking spaces.

Paul Minett and John Pearce used modeling techniques to calculate that bus and single occupancy vehicles use 24 percent more energy than casual carpooling based on participation and ridership in the Bay Area, amounting to annual cost savings of \$30 million.

Safety

Though slugging benefits the environment and saves time and money, safety can be a concern when accepting or giving rides to strangers. As noted, casual carpooling succeeds when the HOV lanes require three-person occupancy. In areas with HOV-2 lanes, or a minimum requirement of two persons in each vehicle, casual carpooling has not been as popular. Many observers attribute this to the perceived safety of being with two other people instead of just one. However, when sluggers discuss safety, they more often refer to concerns regarding safe driving.

Drivers who consistently drive recklessly or unsafely are soon called out on the local casual carpooling Web sites (www.Slug-Lines.com in Washington, D.C.; www.ridenow.org in the Bay Area). Erratic, aggressive, or even strange-acting passengers are also described on the message boards. People in the slug lines can wave off or pass a ride offer without negative consequences if they feel unsafe or uncomfortable entering a particular vehicle. The Scan researchers speculated that safety issues were minimized in the Washington, D.C., area since most of the slugs are government employees with similar dress codes and often wearing federal ID badges.

Role of Transportation Officials

Most regional and local transportation officials have little involvement with the existing self-managed slugging communities. Some, however, actively discourage slugging because they believe that the practice negatively influences public

transportation usage and revenue. In the Bay Area, the Bay Area Rapid Transit (BART), concerned about this issue, takes steps to ensure that casual carpoolers do not use the parking lots reserved for public transit customers. They have designed some park and ride lots so that to pay for the parking, users must first pay for a BART ticket, thereby eliminating any financial benefits to slugging and reserving the park and ride lots for paying customers. At the same time, the Metropolitan Transportation Commission (MTC) provides a link to the local slugging Web site, and in 2007, Randy Rentschler, then director of legislation and public affairs at MTC, asserted that carpooling composes the largest category of vehicles that pass over the Bay Bridge during morning traffic and was a positive practice that benefited all community members.

In northern Virginia and Washington, D.C., public transit does not have the capacity to meet the needs of all commuters, and local governments have supported the efforts to promote casual carpooling. The Potomac and Rappahannock Transportation Commission (PRTC) actively encourages casual carpooling by disseminating information and advising on regard to location placement for slugging queues. Additionally, the Arlington County Commuter Service has provided an annual grant to David LeBlanc, operator of the Web site www.Slug-Lines.com. Researchers in Atlanta, Georgia, and San Diego, California, have conducted studies to explore the possibility of casual or dynamic carpooling to reduce the burden on their congested traffic system. With increasing cuts to public transportation budgets nationwide, casual carpooling and other types of ridesharing might fulfill an important need as capacity is cut.

Advent of Dynamic Carpooling

Casual carpooling is inherently limited by the infrastructure that supports its development. Some consumers might be willing to share rides in areas without the structural characteristics that give rise to slugging. Advances in technology, particularly the high usage of smart phones, allow individuals to quickly arrange rides on short notice. Unlike traditional casual carpooling, participants make plans with particular and known drivers and passengers. Zimride, founded by John Zimmer, which has facilitated long-distance ridesharing, has received \$6 million from Mayfield

Fund to allow drivers to “sell” empty seats in their cars. Riders pay a fee through the Zimride service, and the driver is compensated minus transaction fees. An advantage of this system is that participants are not limited by set pickup/dropoff locations. To allay safety concerns, users of the system must verify they are associated with participating corporations or universities. They must also link their Facebook account. Either drivers or passengers can pass up the match based on the information contained in the user’s account.

Paul Minett, chief executive officer of Trip Convergence based in New Zealand, is also trying to facilitate dynamic ridesharing both in his home country and within the United States. Though the technology-based services provide more flexibility to individuals who would like to share rides, they introduce a commercial element that has been absent from the slugging culture.

Promoting casual or dynamic carpooling can reduce the use of natural resources, diminish harm to the environment, and decrease stress on overburdened transportation systems. New technologies might be able to encourage skeptical individuals to join the slugging ranks.

Chicago Area Transportation Study

The Chicago Area Transportation Study (CATS) was an organization that played a major role in developing regional transportation modeling and significantly shaped the way transportation planning is done in the United States today. Although the first metropolitan-level transportation study was carried out in Detroit in 1953, CATS researched and standardized the process starting in 1955. This work led to the institution of the Metropolitan Planning Organizations that exist in all major US metropolitan areas, as well as the Urban Transportation Modeling System (UTMS) that is key to transportation planning and engineering.

At the time of CATS’ founding, there were already nearly 300 miles of limited access roads built or approved in the Chicago area, but the question remained of how the system would be updated as the region continued to grow. A three-volume study of travel surveys, land use and travel forecasts, and plans for dealing with future growth

was proposed to be carried out within the developed parts of the region. At that time, this included the city of Chicago, the remainder of Cook County, all of DuPage County, and the innermost fringes of Lake and Will Counties. Local, state, and federal funding contributed to the establishment of CATS as an independent organization, and its board included no elected officials in an attempt to remain politically neutral.

At the start of the process, members of CATS and relevant jurisdictions realized that some of the data they were using had not been updated since the 1930s, so not only would they need to carry out intensive data collection, they also would need to develop an institution that would ensure those data were updated regularly.

However, the data collection soon proved too intense to be easily repeatable. Interviews were conducted with 57,000 households across the region, about 1 in 30 of those in the metropolitan area. Cordon interviews gathered data from 200,000 travelers in trucks and cars at multiple entry points into the Chicago metropolitan area. Surveys were conducted with 9,000 rail commuters with the assistance of the then privately owned railroads, and a survey of boat captains on the Sanitary and Ship Canal was done as well.

Finally, CATS carried out a never-before-done land use survey of the metropolitan region. Over 300 temporary employees carried out the various surveys at a cost of a million dollars in 1956, and the study itself was not completed until 1962. Ironically, despite the beginning goals, the intensive nature of data collection has made it a feat that has never been replicated.

Outcomes

Nevertheless, the survey and its subsequent analysis did have other long-lasting effects. CATS pioneered a 10-step process of what has since come to be known as the rational planning model: data collection, data analysis, forecasting, establishing goals, designing alternatives, testing alternatives, evaluating alternatives, selecting an alternative, implementing the alternative, and monitoring the alternative. This rational planning model is still the foundation for most American transportation planning. Staff in CATS had backgrounds in planning, sociology, economics, mathematics, journalism, geography, and engineering, leading to an unusually

multidisciplinary approach that strengthened the development of the planning model.

There were tangible outcomes as well. Within Chicago, notable impacts of the three-part study include the implementation of three recommended rail lines in the 1960s and 1970s: the Skokie Swift, the Red Line in the median of the Dan Ryan Expressway, and the Blue Line in the median of the Kennedy Expressway. At the same time, none of the recommended expressway additions were made, including the Crosstown Expressway that would have run north-south east of Cicero Avenue from the junction of I-90 and I-94, past Midway Airport, and then east near 75th Street.

The project was successfully fought in the 1970s by community groups who had already seen thousands of housing units lost to regional expressways. The shift from expressway projects to transit at this time was hardly unique to Chicago, demonstrating that even the rational planning model had its limits in terms of translation from computers and maps to concrete and pavement.

Urban Transportation Planning

At the same time that CATS was developing what is known today as urban transportation planning, the federal government was moving toward the same regional approach to managing population and traffic growth. The 1962 Federal Aid Highway Act included the proviso that metropolitan areas with populations over 50,000 would not receive federal highway aid unless there was a continuing, comprehensive, and coordinated planning process in place. By 1965, this requirement had expanded, and projects proposed by a local government that could receive federal funding had to be approved by a regional agency to ensure they fit into the regional plan. Since CATS already existed, it slid into this role.

In 1973, Congress established and funded Metropolitan Planning Organizations (MPOs) to fill this role in a more standardized fashion across the country and to provide regional organizations with more authority over state and local governments by requiring MPO approval for the disbursement of federal transportation funds, as well as a 3–5 year plan that included both highway and transit projects. Again, CATS was designated as the official MPO for the six-county region, now with one elected official from the Council of Mayors on its board.

Agencies

The Chicago region is well known for its intensive fragmentation of local governments, and regional transportation planning is no different. As CATS was working on its initial study in 1957, the Illinois General Assembly was creating another agency, the Northeast Illinois Planning Commission (NIPC), to study regional planning and assist local governments. If CATS was founded to understand the transportation and land use patterns of the Chicago region and predict and provide for their future needs, NIPC was founded to deal with the extreme fragmentation of local government that made transportation and land use such difficult issues. As an advisory body, NIPC did not have the stick of federal transportation funding access to wave at local governments, but rather it provided the carrot of cooperation in local planning concerning water, open space, and stormwater. Larger than CATS, NIPC covered a six-county region (Cook, DuPage, Kane, Lake, McHenry, and Will).

As time went on, NIPC took on the role of forecasting population and traffic via funding from the National Housing Act, while CATS carried out the MPO functions of disbursing federal transportation funds. The two agencies collaborated closely and were even located across the street from each other in Chicago's Loop. By 1994, the agencies worked together directly to produce a single regional transportation plan, projecting out to 2020. This planning process led to discussions of merging the two agencies to better integrate transportation and land use planning within the region. In 2005, the state legislature passed the law that merged the two into the Chicago Metropolitan Agency for Planning (CMAP), despite concerns from some local governments that Chicago would gain too much power in the process, as representatives were to be apportioned by population.

Unlike CATS, the CMAP board members are appointed by elected officials, one-third each from Chicago, Cook County, and the six remaining counties of the metropolitan area taken together. Currently, CMAP has 102 employees and a budget of \$15.7 million. The original proposal would have also brought into CMAP the Regional Transportation Authority (RTA), the agency that oversees bus and rail transit in the region, in order to integrate public transportation with traditional land use and transportation planning. Although that effort

failed, there has been renewed interest in the early 2010s in incorporating the RTA.

Effects

One of the most lingering effects of CATS has been the development of the travel demand forecasting model: trip generation by zone, modal split, trip distribution among zones, and traffic assignment. The Bureau of Public Roads, which later became the Federal Highway Administration (FHWA), expanded upon CATS's work to produce the familiar Urban Transportation Modeling System, or UTMS. Another significant contribution was to link land use forecasting to transportation planning, although the chicken-and-egg question of which should be taken first in modeling the other remains to be solved.

At the same time, a significant criticism of CATS is that the quantitative emphasis of the study's work claimed to be value neutral. However, the practice of extrapolating current trends and providing sufficient infrastructure to meet those trends did not consider if the current transportation and land use needs of those outside the middle-class, white, able-bodied population were being met. The assumption of the individual, rational actor led to mapping "desire lines" that demonstrated current travel patterns while assuming those were the optimal patterns to be achieved in the future. This "predict and provide" model has been critiqued as claiming to be value neutral when it actually is not. In contrast, a "predict and decide" model would offer possible scenarios for dealing with future populations and employment growth rather than simply expanding existing infrastructure.

The individual, rational actor was also a problematic assumption, considering the racial segregation written into housing covenants in much of the region, the large-scale federal subsidization of suburban expansion via Veterans Administration and Federal Housing Administration loans, and the gender segregation that existed at the time in terms of daily travel behavior. Nevertheless, the legacy of CATS in terms of linking land use and transportation, as well as taking a multidisciplinary and multi-jurisdictional approach to transportation planning, changed the way that metropolitan areas developed across the country and beyond.

educational, and leisure destinations. Transportation policies can also generate equity problems because poorer persons can't use existing networks to get to these and jobs or exploit other resources. At different times, social movements have arisen to challenge established patterns of accessibility to transit, in terms of the rights of passengers and the extent to which existing transit services meet given transit dependents' needs. A particular focus is on how African Americans and other disenfranchised minority groups can gain political power over decisions in the mass transportation system.

One starting point is the historical legacy of racial discrimination and unequal access to power in U.S. history. The Civil War ended in 1865, but despite passage of the Fourteenth Amendment guaranteeing equal legal protection to all citizens, beginning in 1881 and through the 1940s, localities and states in the South adopted various laws that mandated racial segregation in public transportation and eventually virtually all aspects of life. This system, codifying existing behaviors and customs, was known as Jim Crow.

The U.S. Supreme Court sanctioned the practice in the infamous 1896 *Plessy v. Ferguson* case. Mark Newman (2004) notes that "the anonymity of urban living and the racial equality implied by shared use of new forms of public transportation led whites to segregate the races by law, so that previously established but unwritten 'rules' governing behavior between the races received legal sanction." This created an eventual political base for the Civil Rights Movement and its efforts to overturn the *Plessy* decision and achieve equality in transportation and other spheres.

The Montgomery Bus Boycott and the Civil Rights Movement

An early example of direct action to promote mass transit civil rights in the South took place in June 1953. At that time, the Reverend T. J. Jemison took the lead in organizing a boycott of buses in Baton Rouge, Louisiana. The week-long boycott led bus seating to be allocated on a first-come, first-served basis. African Americans would no longer have to give up their seats to whites. In December 1955, Rosa Parks was arrested for refusing to sacrifice her seat to a white man on a crowded bus. Parks was a member of the Montgomery National Association for the Advancement of Colored People (NAACP) and

Civil Rights and Transportation

Transportation has become a civil rights issue because there can be an uneven distribution of access to public transportation services by minority residents needing to reach shopping, work, medical,

After attending an event in Dearborn, Michigan, on April 18, 2012, President Barack Obama took a moment to sit in the bus that Rosa Parks made famous in December 1955. Because of its importance to the Civil Rights movement, as well as to the history of transportation in the United States, the bus has been preserved at the Henry Ford Museum.

attended the Highlander Folk School (a social justice leadership training center) in 1955. Her arrest led to a boycott of the Montgomery bus system.

Edgar Daniel Nixon, who paid Parks's bond, and the Women's Political Council (WPC) developed the idea for the boycott. The WPC comprised 300 middle-class African American women. Their activities included voter registration and putting pressure both on the city of Montgomery to hire African American policemen and on merchants to desegregate the use of public drinking fountains. After Parks was arrested, Nixon brought up the idea of a boycott to prominent local African Americans. The WPC began to organize the boycott on the day of Parks's trial. Jo Ann Robinson, a professor at all-black Alabama State College and WPC president, publicized the protest by preparing and distributing 40,000 mimeographed handbills, while Nixon sought support from local black clergy. The support

of religious leaders was key because of the respect ministers enjoyed and their authority among all classes. They were also economically independent of whites. Under political pressure from activists and the growing turn of events, the majority of the city's initially reluctant African American clergy endorsed, publicized, and helped organize the boycott. Parks was convicted and fined, but over 90 percent of African American bus riders observed the boycott.

This strong community support led church and secular community leaders to create the Montgomery Improvement Association (MIA) to maintain the boycott until demands were met. These included hiring African American bus drivers for black neighborhoods; first-come, first-served seating; and more courteous treatment. On Montgomery buses, whites had claim to the first four rows of buses, with blacks limited to the rear even though

they comprised more than 75 percent of bus system riders. Blacks could take middle seats until they were needed by whites. They then had to move to seats in the back, stand, or leave the bus if there was no room.

The MIA chose Martin Luther King, Jr., as its president, and he became a central figure in the successful boycott, which lasted 381 days. The campaign ended shortly after November 13, 1956, when the U.S. Supreme Court outlawed segregation on Montgomery's buses in the case of *Browder v. Gayle*. These events not only captivated the United States but also helped transform King into a national leader.

Legislation, Regulations and Policy Proposals

The efforts of the Civil Rights movement are partially reflected in legislation governing the Department of Transportation (DOT). The DOT has a Departmental Office of Civil Rights (DOCR) which enforces regulations and laws that prohibit discrimination on the basis of age, color, disability, national origin, race, religion, and sex in both employment and the provision of government services. This office helps ensure that recipients of DOT funds carry out federally assisted activities and programs in a nondiscriminatory manner.

The civil rights–related activities that the DOT enforces through DOCR include Titles VI and VII of the 1964 Civil Rights Act as amended, the Equal Pay Act of 1963, the Age Discrimination in Employment Act of 1967, and Section 504 of the Rehabilitation Act of 1973, as amended. Title VI prohibits discrimination by those transit providers receiving federal financial assistance on the basis of color, race, and national origin, including denial of meaningful access for persons with limited proficiency in English.

The DOT can also issue administrative rules that promote civil rights and social justice objectives. For example, in November of 2013 Anthony Foxx, U.S. Secretary of Transportation, announced that his agency would require automated airport kiosks and airline Web sites to be accessible to passengers with disabilities. The DOT also issued regulations related to storage of wheelchairs on passenger aircraft. The DOT Order on Environmental Justice (DOT Order 5610.2 (a)) represents a complement to civil rights legislation by creating a process by which the DOT and the Federal Transit Administration (FTA)

integrates environmental justice goals into existing operations. This helps ensure that such goals are considered in activities, policies, and programs at various stages of planning.

Both Title VI and DOT regulations prevent federal-aid recipients from intentionally discriminating against people on the basis of color, race, and national origin. DOT rules and regulations enforcing Title VI also make clear that even policies or practices that unintentionally produce “disparate impacts” on minority populations or “disproportionate burdens” on low-income persons are prohibited.

Transit agencies monitor their performance in carrying out civil rights practices in a variety of ways. One way is to study demographic ridership and travel patterns. In some cases, fixed-route providers of public transportation that meet certain thresholds are obligated to collect information from riders on race, color, national origin, language spoken at home, English proficiency, and travel patterns of their rides by using customer surveys. Providers of transit are obligated to use such information to compare minority and nonminority riders in terms of demographics and trips taken. Moreover, demographic information about fare transit usage among low-income and minority users is collected to assist with assuring fare equity.

Transportation development and equity policies can be used as a way to promote the democratic access to resources. Fair housing advocates have supported new policies to increase development of new affordable housing and preserve affordable housing in the immediate vicinity of a newly funded transit stops. The FTA supports affordable housing and so explicitly recognizes the linkages between housing and transportation. FTA funds can influence urban development and housing patterns. Such funds can influence the extent to which open housing opportunities for protected classes are promoted (a stipulation of the Fair Housing Act) or whether barriers to fair housing are created.

The Leadership Conference on Civil and Human Rights (2011) argues that “transportation policy has the potential to expand economic opportunity for low-income Americans and underrepresented workers by connecting them to highway, transit, and rail construction jobs.” It notes that “transportation spending generates jobs for workers in the

construction industry and also has indirect effects on job creation by increasing the efficiency of the transportation system and improving business productivity.”

Transportation Equity, Economic Development and Civil Rights

When transportation developments promote gentrification and displacement of certain communities, equity problems may emerge as poorer communities may lose while wealthier income groups can gain. After World War II, highway projects cut through minority urban neighborhoods to shuttle commuters to and from suburban areas.

K. H. Shaeffer and Elliot Sclar (1980) write that “the quality of human life depends on the amount of access we have to one another.” The collocation of work and community living may create access, as can mobility but, they argue, “mobility and access are not the same.” When work and community are divided, however, access can be essential, creating problems when certain groups dependent on public transit are segregated in neighborhoods that do not have proximate access to jobs. Accessible mass transit then becomes essential for employment, economic power, and hence the political power that economic participation brings. Some communities may also be denied their fair share of public transit investments or be forced to pay more for transit services than they can afford.

Equity advocates like Wade Henderson, Leadership Conference president and chief executive officer (CEO), has argued that “millions of low-income and working-class people, people of color, and people with disabilities live in communities where quality transportation options are unaffordable, unreliable, or nonexistent.” A basic problem is that the average cost of owning a car is somewhat less than half of the federal poverty income level for a family of four. As a result, in recent years one-third of low-income African American households didn’t have automobile access, in contrast to 25 percent for low-income Latino families and 12.1 percent for white families. Budgetary policies can lead to equity problems because while the federal government has allocated about 80 percent of its transportation funding to highways, racial minorities have been four times more likely than white Americans to use public transportation to get to their jobs. Many jobs suitable for welfare-to-work

participants have not been accessible by using public transportation. A large share of the jobs in the largest metropolitan areas in the U.S. lie 10 miles or more beyond the urban core. Therefore, equitable access has been linked to increased investments in mass transit and comprehensive networks including and linking such transit to pedestrians, bicycle paths, and roads.

Bus Riders Union

Some of the contemporary challenges in transportation equity have been addressed by the Bus Riders Union (BRU). Also known as *Sindicato de Pasajeros*, the BRU began operating in 1992 as part of the Los Angeles-based Labor/Community Strategy Center’s Transportation Policy Group. This initiative began by organizing bus riders in a campaign to fight against racial discrimination, which the group argued was reflected in the policies of the Los Angeles County Metropolitan Transportation Authority (MTA).

In 1994, the BRU led protests against a large fare hike and MTA plans to develop a commuter-oriented, regional rail transit network, obtaining a temporary restraining order to stop the MTA. BRU sued the authority for violating the civil rights of bus riders dependent upon buses. That year The Labor/Community Strategy Center and BRU, together with other community and civil rights organizations, sued the MTA in 1994 in federal court for violating the civil rights of public transit riders who depend on buses, obtaining a temporary restraining order to stop the MTA’s fare increase. They charged that the authority had violated Title VI of the 1964 Civil Rights Act, the provision prohibiting government agencies, receiving federal funds from distributing them in a racially discriminatory manner. The MTA was accused of creating “a separate and unequal mass transit system—a dilapidated, overcrowded bus system for 400,000 overwhelmingly Latino, Black, and Asian/Pacific Islander bus riders.”

In 1996, the BRU and other advocacy groups filed a civil rights lawsuit that said that the MTA had not done enough to keep fares affordable or to prevent overcrowding. A settlement agreement between the parties resulted in a civil rights consent decree that mandated federal court oversight of the system for the next decade. It also required the MTA to spend \$1 billion to add new transit lines

and more buses on existing routes. The mandated oversight expired in 2006, only to be followed later by cutbacks in bus service that promoted hardship in minority communities. More recent BRU initiatives have focused on fighting fare hikes and promoting dedicated bus lanes.

Clean Air Act and Amendments

The Clean Air Act of 1970 (CAA) was the first major comprehensive, substantive engagement by the federal government with the human and environmental health effects of pollution. The act, administered by the Environmental Protection Agency (EPA), created uniform nationwide enforceable air quality standards. It designated two primary categories of polluters subject to regulation: stationary sources, (primarily industry) and transportation "mobile sources." For over four decades, the CAA has coevolved with all aspects of our transportation systems and is now embedded in decisions ranging from fuels and vehicle design, systems planning, and modal selection to infrastructure project funding, design, construction, and operation.

These transformations have been facilitated by the development of robust administrative networks involving the EPA, the U.S. Department of Transportation (USDOT), state departments of transportation and environment, metropolitan planning organizations (MPOs), and the broad spectrum of transportation industries. This robust framework plays a central role in improving sustainability in a period of continuing economic and environmental change.

Comprehensive pollution management involves a systems approach integrating sources—pathways/receivers. This is particularly challenging in a nation as large and complex as the United States with millions of vehicles, numerous unique land use and meteorological regions, and a spectrum of human health, ecological, and built environment receivers that may be impacted by airborne pollutants. The CAA requires the EPA to regulate the National Ambient Air Quality Standards (NAAQS). In 1970, scientific and technical understanding of all components of these systems and

their interactions was poor. NAAQS cover six basic airborne pollutants: carbon monoxide (CO); lead; nitrogen dioxide (NO₂), ozone (O₃); particulates; and sulfur dioxide (SO₂). Photochemical smog is an atmospheric product involving many components, including NO₂, O₃, and particulates from vehicular sources.

The CAA was revolutionary in its use of federalism to meet the newly established air standards. The EPA conducts research and establishes standards. Governors of each state designate “air quality control regions” approved by the EPA. States monitor air quality and submit annually to the EPA whether the regions were in “attainment” or “non-attainment” for each pollutant. The EPA provides technical, financial, and educational assistance to the states to ensure that the data generated is valid for regional management and that it can be aggregated for national air quality modeling, policy analysis, and program evaluation.

From 1970 to 1990, the primary transportation air pollution focus of the EPA was on national vehicle emissions reduction. The CAA’s NAAQS primary regulations are based solely on the health of receivers, such as lead exposure in children. However, the CAA states the means by which these standards are met must consider effects on the economy. The Supreme Court has interpreted the Clean Air Act as a “technology-forcing” law, meaning the EPA can set industry requirements that are technically feasible but not currently widely used. The timing of implementation of pollution-reduction mandated actions is often extended.

The EPA and DOT began voluntary measurements of fuel efficiencies for new autos, sport utility vehicles, and light trucks for each manufacturer to determine a baseline. In 1975 the EPA mandated a 100 percent improvement in Corporate Average Fuel Economy (CAFE) levels by 1985. Other CAA transportation initiatives include elimination of lead additives in fuel, development of biofuels; evaporative controls on gas tanks; catalytic converters; and standards for jet aircraft engines, diesel, and outboard engines and off-road vehicles.

Clean Air Act Amendments

A central focus of the 1990 Clean Air Act Amendments (CAAA) was urban air pollution, smog, and CO from mobile sources, which had continued to increase since 1970 despite CAFE standards, due

to growth of metropolitan populations and vehicle miles traveled (VMT). The CAAA gives the EPA increased authority and requires it to review new science and to update regulations on a five-year cycle. States must implement monitoring, planning, and enforcement programs.

A State Implementation Program (SIP), updated every three years, provides a unified framework for statewide and regional programs. Air quality in management regions that meets NAAQS is classified as “maintenance”; decreases in this air quality level are not allowed. Regions that do not meet standards are classified “nonattainment” and are rated on a hierarchical scale from “moderate” to “extreme.” The ratings determine the extent and timing of the mandated SIP programmatic actions to achieve “conformance.” The SIP includes both statewide and regional air quality conformance elements. A key SIP component for nonattainment regions is the motor vehicle emission budget (MVEB), the fraction of total regional air emissions that is allowed from mobile sources for each pollutant.

In 1991, the Intermodal Surface Transportation Efficiency Act (ISTEA) declared that the nation’s integrated transportation system shall include significant improvements to achieve national goals for improved air quality. ISTEA is proactively multimodal. To implement CAAA, it broadly expands the role of metropolitan planning organizations (MPO). MPOs are assigned the responsibility to certify that both their Long Range Transportation Plan and the projects within their annual Transportation Improvement Program (TIP) are in “conformity” with the SIP’s MVEB for their air quality region. These analyses are done by integrating EPA-developed air pollution models with MPOs continuing Traffic Demand Model modeling. Outputs estimate future VMTs. While smog is a regional phenomenon related the metropolitan system, unhealthy CO levels can be highly localized. To address the latter, projects involving vehicular traffic CO “hotspots,” such as highly congested intersections, undergo specialized studies as a basis for conformity designation.

States and MPOs have numerous alternatives to achieve reductions in VMTs and emissions. Traffic control measures for existing vehicular systems, such as designated bus lanes and “smart signals,” can be used to upgrade existing facilities. New

multimodal projects, such as light rail and bicycle commuting, play an increasing role in achieving conformance. These initiatives can synergistically stimulate “smart growth” and other local and regional land use management innovations that help reduce vehicular travel demand.

Analysts agree that the CAA has been the primary driver in the continuing transformation of the nation’s transportation system toward the goal of environmentally sustainable performance. In 2011 an agreement was reached to double current CAFE fuel efficiencies by 2025. Complex transportation nodes such as major airports and international container ports that integrate shipping, rail, and truck traffic are subregional “hotspots.”

Specialized operations analyses and monitored demonstration projects are under way to develop integrated air quality management approaches for these facilities that must rapidly respond to global economic change. New CAA transportation challenges continue to emerge, such as the impact global warming will have on photochemical smog creation and the role transportation will be assigned by the government in controlling greenhouse gases.

Climate Change, Transportation Adaption to

Impacts from climate change occurring now and those projected for the future pose considerable and escalating threats to transportation systems, including bridges, highways, tunnels, railways, buses, heavy and light rail vehicles, ferries, and so forth. They exact a tremendous toll on the financial and social capital resources of transportation agencies—from national and state transportation departments to metropolitan planning organizations and local public transit authorities—when they influence service disruptions, equipment failures, and infrastructure loss. As a result, the ability of transportation agencies to provide safe, reliable, and efficient travel resources and services for all segments of society for the purposes of social and economic development and safety becomes limited or erased all together. In the effort to avert future impacts and to sustain and improve the transportation systems they steward, transportation agencies nearly everywhere are considering and turning toward climate change adaptation as a solution.

Climate Change Adaptation Defined

Adaptation is broadly defined in global environmental change research communities as all cultural, economic, political, and physical approaches a society implements to reduce the burdensome and devastating effects of current and projected climate regimes on natural, built, and social systems. This concept is understood as an iterative process in which harmful hazard conditions are mediated with available capital and social resources to maintain or acquire a desired advantage.

Climate change adaptation measures fall into several categorical types, including reactive, autonomous, planned, or a combination thereof, depending on the factors that motivate their implementation. Typically, reactive adaptation is characterized by unplanned, under-resourced, and often ineffective responses to an immediate hazard crisis. It provides short-term relief rather than long-term protection and resilience to quantitatively and qualitatively more impactful events that occur in the near and distant future. With reactive measures

or quickened hazard responses comes also the possibility of exacerbated physical and social vulnerabilities to extreme weather and climate impacts, as managers may not hold a position to fully consider and account for each possible decision outcome with the narrow time they possess. Highly independent responses on the part of institutions, firms, neighborhood communities, and households are said to be autonomous.

Since it is approached independently—and reactively in some cases—autonomous adaptation carries strong potential for creating individual, communal, and institutional conflicts in the present and future. In comparison to the aforementioned, planned, or what is also known as proactive, adaptation is perhaps the most ideal and desirable. Planned adaptation involves greater and more conscientious use of space and time to investigate place-based and social vulnerabilities, brings together communities and institutions to discuss and weigh decision-making consequences, and enhances their ability to acquire and utilize resources toward dealing effectively, efficiently, and cooperatively with climate impacts long before they are encountered.

Transportation System Vulnerability

In a global society, the interconnections and interdependencies of transportation systems interact in complex and complicated ways where the weaknesses and failures of those in one locale are shared and even driven by those in another. This creates cause for concern among practitioners, policy makers, scientists, and citizens because the fates of environment and society are firmly intertwined. Scientific evidence indicates that extreme weather is spreading in magnitude and impact as a result of natural and human-caused climate change. Likewise, polar glaciers are melting due to the effect of warming and rising seas.

The force of these trends is demonstrated through higher hurricane and cyclone intensities and elevated storm surge heights that produce spectacular coastal and inland flooding in the Eastern and Western Hemispheres. At highest risk are transportation systems located in the middle latitudes where hurricanes and cyclones commonly occur; they suffer high degrees of wear and tear due to environmental and population pressures, and transportation agencies face overwhelming fiscal,

political, and operational challenges in maintaining and operating them on a near daily basis.

Transportation systems are constantly exposed to weather and climate impacts. All bridges, roadways, airport runways, tunnels, rail networks, etc., are subjected to ambient air temperatures, making them highly susceptible to freeze–thaw weathering and short- and long-wave cooling and heating periods that can cause them to destabilize, buckle, and break altogether. For example, softening permafrost—upon which most of Alaska's road, airstrip, and bridge foundations rest—due to rising global temperatures leads to subsidence that causes transport infrastructure to tilt and eventually break apart. For London's Underground rail system, Brian Arkell and Geoff Darch found higher incidences of rail buckling, service delays, and financial costs during the city's hottest summers. Also, temperatures on subway station platforms are generally higher compared to above-ground conditions and can affect respiratory health, particularly for commuters with asthma and the elderly who wait for trains where there are low-performing or no ventilation and cooling systems.

Geographic circumstances heavily influence transportation system disruptions and losses. Many systems are closely located near creeks and rivers, in floodplains, and coastal zones as a consequence of human settlement patterns and available land that governments grant through right-of-way privileges to transportation agencies to maintain and expand service. Location is thus a key factor in the vulnerability of transportation systems to climate impacts.

In 2012, for example, Hurricane Sandy, the biggest Atlantic hurricane on record in diameter and second most costly in financial terms, affected 40 percent of the nation's mass transit riders when rain downpours and coastal and riverine flooding ruined a quarter of New Jersey Transit's rail fleet and substantial stretches of its track network, crippled critical nodes in the Port Authority of New York and New Jersey's (PANYNJ) line system, and caused heavy damage totaling in the billions for New York City's Metropolitan Transportation Authority's (MTA) subways. For Rockaway, Queens, the loss of public rail service left thousands of mass-transit commuters isolated for several weeks until the MTA activated free yet limited shuttle service to this coastal peninsula.

Adaptation in Practice

The problem of transportation system vulnerability contains many geographic and spatial dimensions and is being addressed by governmental and nongovernmental institutions through socially and technically focused adaptation approaches. For instance, the U.S. Department of Transportation, Transportation Research Board of the National Academies, and other relevant institutions provide planning and research literature, conference gatherings, and other information-sharing vehicles to public and private sector transportation agencies for dealing with actual and projected climate change impacts. In 2011, the Department of Transportation's auxiliary agency, the Federal Transit Administration, piloted an adaptation assessment program for regional and local mass transit agencies and their institutional partners that served to further individual agencies' planned efforts and to promote and stimulate peer learning.

Executive orders and state legislation in recent years have helped establish stakeholder groups composed of climate scientists, social researchers, corporate firms, planning departments, nonprofit organizations, and members of the general public to foster a generalized understanding about climate change adaptation for different economic sectors (for example, agriculture, ecosystem services, energy, etc.). Vulnerability assessments are conducted and monitored by advanced groups. Modeled after the United Nations' Intergovernmental Panel on Climate Change, the work of state and local initiatives, such as ClimAID, the New York City Panel on Climate Change, New York State Climate Action Council, and others supports the development of stakeholder agreements for climate change adaptation among transportation agencies and their institutional counterparts.

Establishing regional bodies with cooperative agendas remains a challenge across many parts of the United States because of territorialized municipal jurisdictions. The absence of regional coordination has emerged as a critical issue among advocates because adaptations made in one municipality are perceived to produce negative spillover effects elsewhere.

Technical fixes are a rapidly growing and critical aspect of transportation adaptation to climate change. For example, advanced cooling technology that reduces the effects of permafrost thawing on

These raised flood mitigation filters were installed in Queens, New York, after a 2007 storm flooded subway lines. The sculptured subway vents double as public art and can serve as benches.

road surfaces was developed and piloted through a collaborative agreement between Alaska's Department of Transportation and Public Facilities and the University of Alaska. Inventive street furniture designed to raise the heights of sidewalk vents to prevent future subway tunnel flooding was the response of New York City's MTA to a thunderstorm in August 2007.

Step-ups were also placed at entrance locations to lessen water infiltration for subway stations. Vent shaft systems manufactured by the for-profit firm FloodBreak and balloon plugs designed by the Northwest National Laboratory and U.S. Department of Homeland Security's Science and Technology Directorate to hold back floodwaters represent the next generation of flood control solutions for the protection of subway systems from intensifying and more frequent heavy precipitation events.

For bus systems, commuter exposures to harmful sun rays, storminess, and variable temperature extremes are amplified by the absence of waiting shelters at passenger pickup locations. In urban, suburban, and rural environments, this is a common occurrence due to their physical demand and capital supply challenges. In Palm Beach and Broward Counties in Florida, federally sponsored economic stimulus initiatives in recent years have enabled these municipalities to reduce bus riders' vulnerability to weather and climate stress through the purchase and installation of much-needed shelters in neighborhood communities.

Innovative technologies that monitor, communicate, and manage climate hazard risk have grown ubiquitous among transportation agencies. Managers of operational control centers turn to national, state, and local climatological and meteorological reporting instruments to decide whether, where, and when to provide public access to transportation systems when extreme weather patterns accumulate. A large number of public transportation authorities transmit weather-related travel advisories and voluntary and involuntary transit system disruptions through Web sites and Short Message Service (SMS) texts to the general public. Although not directly motivated by climate change or extreme weather impacts, the Southeastern Pennsylvania Transportation Authority's (SEPTA) in-house-designed digital TransitView application provides customers with real-time bus and trolley route information and gives the agency added ability to manage their service expectations. SEPTA and other similarly situated agencies have also found GPS technologies to be of purposeful benefit toward ordering and organizing transit vehicle operations, enhancing system resilience, and curtailing equipment maintenance and damage costs.

In-house organizational assessments are a key yet underdiscussed aspect of transportation adaptation to climate change. The realization of hidden assets and capacities to reduce climate vulnerabilities likely saves costs in planning time, effort, and resources. For instance, PANYNJ discovered that prior and unrelated capital improvement investments yielded unintended benefits toward addressing projected impacts while conducting a climate change vulnerability assessment. The installation of new barriers and walls for security projects is

now understood by PANYNJ to provide added protection to possible storm surges for its vulnerable infrastructure. Asphalt mixes developed by staff engineers were found to be resilient to vehicle load and extreme temperature stress. Blackouts in recent years resulted in the agency's linking electrical substations to create redundancies that safeguard against future incidents. This technological hazard response is believed to reduce interruptions in electric service from increased cooling demand in a warming world.

Finally, the real-world practice of transportation adaptation to climate change has outpaced scientific research. Peer-reviewed journals have published a mere handful of studies in recent years that deal directly and solely with the topic. At present, scientific knowledge largely consists of research that classifies different actors and their proposed roles in adaptation, evaluates transportation managers' awareness of climate change impacts on transportation systems, and demonstrates the application of methods to visualize adaptation opportunities for short- and long-range transportation planning.

Potential Impacts on Environment and Society

With all the social, economic, political and technological benefits it is intended to create, transportation adaptation to climate change has foreseeable downsides as well. As stated earlier, there are numerous ways to adapt transportation systems to extreme weather and climate change trends, ranging from the abandonment and relocation of hard infrastructure assets (for example, rail lines, stations, etc.), modification of natural environs, and shift or closure of route service, to the use of mobile technologies to announce voluntary system shut-downs for stormy weather and mainstreaming climate change into state-of-good-repair practices, to name just a few. The open nature of transportation systems, however, makes adaptation outcomes highly unpredictable.

Meteorological and physical change processes are dynamic and interact in surprising ways. There is the high likelihood that adaptation for one transportation system can produce vulnerability in another because they vary in size, design life, material composition, age, and population use. Furthermore, adaptation has unpredictable effects for different social groups, places and economic

sectors because their exposures, sensitivities, and adaptive capacities to system disruptions are highly uneven.

Transportation adaptation to climate change invites incalculable risk and impact potential, which can limit and undo complexly linked goals of environmental protection, urban economic development, and hazard safety and risk mitigation. For example, trees are vital to the strength and balance of natural as well as urban ecosystems. Tree-cutting and removal programs aimed at preventing downed energy-transmission lines for rail operations from weather-induced tree toppling can potentially increase stormwater runoff and accelerate the generation of soil pollutants that spill over into fisheries and recreational areas for swimming. Such programs also conflict with efforts aimed at slowing and reversing human-caused global warming, as trees absorb carbon dioxide, a leading greenhouse gas contributor.

New facility construction and retrofitting projects can reconfigure travel spaces and flows in cities and their close-in suburbs to unwanted economic effect for business firms, hourly wage workers, and others who depend on hassle-free transportation routes for financial stability. People who depend on mass transit and possess limited or no access to mobile technologies run the risk of being stranded at bus stops and rail stations not equipped with public address systems when voluntarily and involuntary service disruptions occur.

Adaptation planning and implementation approaches that emphasize social and economic equity can help advance the goals and principles of environmental justice campaigns that center on the construction of hazard-ready, sustainable, and resilient communities. For planners, policy makers, and all of the agencies responsible for stewarding transportation systems that serve urban, suburban, and rural communities, dealing with climate change impacts will be an important task and challenge for them and for the general public to handle in the months, years, and decades to come.

Climate Change, Transportation Impacts From

Research indicates that average global temperatures are increasing. The 10 hottest years on record have occurred since 1998. The hottest year for the contiguous United States was 2012. The hottest La Niña year globally was 2011. Tied for the hottest years globally were 1998 and 2010. March 2012 broke 30,000 heat-related temperature records. Arctic sea ice melt accelerated during the past three decades and reached its lowest extent in 2012. General circulation of the atmosphere and precipitation patterns have been altered with a general decrease in precipitation at lower latitudes that already are arid and semi-arid and a general increase in precipitation in middle- and high-latitude locations. Extended droughts prevail in some areas, with more frequent flooding in others.

Higher temperatures cause greater evaporation from both soils and from water bodies. Dry soils and heat-stressed vegetation contribute to a greater number and intensity of forest fires. The smoke and low visibility from fires causes massive traffic pile-ups and has prompted highway closures. The increase in evaporation from water bodies adds water vapor to the atmosphere, which fuels storms. Superstorm Sandy and Typhoon Bopha were fueled by higher sea surface temperatures and higher amounts of water vapor in the atmosphere. Superstorm Sandy flooded the subway system of Manhattan in New York City in 2012. Adding heat to the climate system has resulted in a greater number of severe weather events and a significant increase in operating expenses for the transportation industry.

Aviation

Diversions and cancellations of commercial flights result in hundreds of millions of dollars that the U.S. airline industry loses annually largely due to extreme weather. In the northern United States, delays of aircraft full of passengers due to snow and ice accumulations on runways continue to make the headlines. Aircraft accidents can be caused by high winds such as those that accompany severe thunderstorms, and storms are strengthened by unstable conditions that often result from surface heating. Reports from the National Transportation Safety Board show that weather was a causal or contributing factor in 21 percent of the documented 19,562 aircraft accidents between 1994 and 2003. In 83 percent of the accidents involving commercial air carriers, turbulence and wind were responsible. General aviation accounted for 87 percent of all weather-related accidents.

A microburst, which is a localized downburst from a cumulonimbus cloud, is the deadliest of wind-induced aircraft accidents. Since there is very little air space in which to recover, microbursts are especially deadly during takeoffs and landings. There were 26 commercial aircraft accidents and 620 deaths attributed to microbursts between 1964 and 1985. Yet since 1995, numerous airports and all major airlines in the United States have adopted wind shear detection equipment, which has reduced the accident rate substantially. An additional concern for the aviation industry is the location of its airports. Numerous seaports and airports around the world are located near the coasts. With higher sea surface temperatures and thermal expansion of the oceans, sea level rise poses a serious challenge to transportation infrastructure. In conjunction with thermal expansion, scientists are monitoring the movement of glaciers flowing seaward from large ice sheets. This dynamic contribution of freshwater could result in sea level rise of several meters (20 feet). It is estimated that more than half the human population lives within 60 miles of the sea.

Ground Transport

Climate change is forecast to further intensify tropical storms and cause more frequent outbreaks of violent weather with the associated heavy precipitation and winds. Intense surface heating destabilizes the atmosphere and can contribute to heavy rains that are capable of flooding extensive geographic

Hurricane Sandy, the largest diameter hurricane ever recorded in the Atlantic, wreaked havoc on the transportation systems of New York and New Jersey in late 2012, disrupting travel for a full 40 percent of all mass transit riders in the United States. The ramps shown above in Jersey City, New Jersey, on April 18, 2013, had previously been used by ferries at Liberty State Park to carry passengers to Ellis Island and the Statue of Liberty, but they were mostly destroyed by the storm.

areas. Heavy rains also destabilize steep slopes, initiating mass-wasting events such as the mudflows that commonly plague the Pacific Coast Highway in California. Heavy precipitation is a major contributor to automobile accidents.

Transportation problems that are directly affected by increasing global temperatures are abnormally hot days, which are becoming more frequent and extreme. Railroad tracks warp and buckle during significant heat events, sometimes causing train derailments. Concrete highways undergo joint buckling, creating hazardous conditions for motorists, while asphalt roadways are subjected to softening. Approximately 30 billion tons of carbon dioxide is added to the atmosphere annually. Transportation are responsible for approximately one-quarter of greenhouse gas emissions globally and these emissions are growing more rapidly than

those from other sectors. Of that 25 percent, road transport accounts for approximately 70 percent, shipping is responsible for approximately 20 percent, and air transport for 10 percent.

Shipping

In the summer of 2007, the sea ice of the Arctic shrank to its minimum up to that time. The Northwest Passage opened, which connected the Pacific with the Atlantic Ocean north of Canada's Northwest Territories. Russia planted its flag on the sea floor at the North Pole, Canada decided to open new Arctic bases, and offshore development began. While warmer temperatures melt permafrost on land in the Arctic, which inhibits ground transport, shipping industries are viewing the Northwest Passage for mineral exploration and more commercial operations.

As the Great Lakes shipping season begins for 2013, hydrologists warn that shippers should expect low water levels and that they might have to leave some cargo at the dock. In January 2013, water levels in Lake Huron and Lake Michigan reached record lows, with a monthly mean of 576.02 feet. While it is anticipated that they will not break the January record, the water levels are forecast to be well below the long-term average. While all the Great Lakes are below their long-term average and are expected to remain so for the first half of 2013, Lakes Michigan, Huron, and Superior have been below average for 14 consecutive years—the longest duration in history. Low water levels impose navigational hazards for commercial carriers, along with economic ramifications for all Great Lakes interests such as marinas and waterfront restaurants.

Transportation infrastructure is designed, built, and functions in accordance with local climate conditions. In the *Special Report on Emissions Scenarios*, the United Nations Intergovernmental Panel on Climate Change (IPCC) modeled possible future climates based on the decisions made by policy makers and societies. In each of the future scenarios, there is likely to be a negative impact on moving goods and people. The more greenhouse gas emissions are reduced and the sooner the reductions take place, the better chance there will be to keep transportation networks viable.

Collector Streets

The U.S. Federal Highway Administration (FHWA) divides roads into urban and rural based on census designations of urban and rural areas. Urban and rural roads are further designated into three distinct functional classes: arterials, collectors, and local streets. Each function class is based on the type of service the road provides to the motoring public, and the designation is used for data and planning purposes.

The arterials include interstate highways, freeways, and other highways. They connect the nation's major urbanized areas and cities. As the name suggests, collector streets "collect" traffic from local streets and feed it to higher-function roads such as highways. They often connect key community functions such as schools and major commercial establishments in both urban and rural areas.

The local streets include all access roads and neighborhood-level streets. About 11 percent of roads in the U.S. highway system are labeled arterials, 20 percent collectors, and the rest local roads. Design and construction of these roads are dictated by design manuals from federal and state departments of transportation, which specify various standards.

The functional classes of roads can be changed based on changes in traffic and local land uses. Recent trends show that inclusion of "complete street" concepts are increasingly applied to arterial, collector, and local road designs. The construction and redevelopment of these roads are funded through a combination of federal, state, local, and private funding sources.

Functional Classification

Within urban areas, arterials are divided into principal arterial and minor arterial. These roadway categories vary based on the roadway's relationship between mobility and land access. Here, mobility is defined as the ease of movement between points, whereas land access is defined as access to specific properties.

Arterials emphasize a high level of mobility for through movement, whereas local streets emphasize the land access function. Collectors offer the middle path—relatively equal importance to mobility and land access. There are overlaps of function and mobility characteristics between arterials and collectors as well as between collectors and local streets.

Classification is based on a number of factors such as area characteristics (rural or urban), population served, land use in the area, vehicular traffic (measured as vehicle miles traveled, or annual daily traffic), length of the road, and spacing, among others. Arterials provide the highest level of service at the greatest speed for the longest uninterrupted distance, with some degree of access control. The longer a street is, the more likely it is that the street will function at a higher classification.

Typically, arterials will have annual daily traffic (ADT) of more than 10,000. Principal arterials, particularly in urban areas, carry the majority of traffic entering and leaving urban areas, bypass traffic, and other major intra-area movements. They include the entire federal interstate highway system and other urban freeways and expressways. Minor arterials interconnect with and augment the principal arterial network.

Collectors “collect” vehicles from local roads and feed to arterial routes for longer travels or other collector roads. Typical ADT on collector roads is about 1,000 to 10,000. Local roads primarily serve access to homes and commercial/office establishments. They carry less than 1,500 ADT.

Changes in Functional Classification

The federal Highway Performance Monitoring System (HPMS) measures vehicle miles traveled (VMT) by functional class and can be used to understand driving patterns on each class, land development pattern in a region, and the potential damage to the pavement. Traffic patterns on a roadway and the roadway's function can change over time.

The FHWA and state Departments of Transportation (DOTs), with the help of metropolitan planning organizations (MPOs), review suggestions for redesignation and make appropriate changes. Municipalities and county governments can submit such suggestions based on the land use changes or traffic pattern changes in their jurisdictions. The decision to change classification will be based on careful review of changes in conditions and sound reasoning. Such changes can have implications on design of roads and federal and state funding.

Characteristics of Roads

Usually, access to principal arterials is fully controlled and allowed only at interchanges. Directional travel lanes on these roads are usually separated by some type of physical barrier. They are designed and constructed to maximize their mobility function, and abutting land uses are not directly served by them. Other principal arterials have partial access control, which means they can also be used to access abutting land uses. Minor arterials may not have access control.

Generally, bicycles and pedestrians are not allowed on major arterials. In urban areas, major arterials could carry as few as 7,000 vehicles a day. In rural areas, this minimum is 2,000 vehicles a day. Corresponding values for minor arterials are 3,000 and 1,500 vehicles per day.

The collector streets are divided into major and minor collectors. They support both mobility and access functions in nearly equal measure. Major collectors typically have greater right-of-way and pavement widths, and wider traffic lanes than minor collectors. They generally have traffic signals and left-turn lanes at major intersections and driveways.

They also provide raised medians in busy areas to reduce conflicts and provide pedestrian refuge. They usually have sidewalks, planting strips, and bike lanes. They could carry as few as 1,000 vehicles a day in urban areas. Left-turn lanes are only sparingly used on minor collectors, mostly at intersections with higher volume streets. Though they might have sidewalks and planting strips, bike lanes are not necessary. Typically, bikers share the road with auto traffic.

In rural areas, minor collectors could carry as few as 150 vehicles a day and major collectors might carry as few as 300 vehicles a day. Collector streets are also

used as important emergency response routes and are frequently used as transit routes.

Local roads account for the largest percentage of all roadways in terms of mileage. They are intended for accessing land parcels from collectors and vice versa. Bus routes, bicycle paths, and sidewalks generally do not run on local roads and they are the narrowest streets among the three classes. There is no access control or division between lanes in opposite directions. They usually carry no more than 750 vehicles per day.

Highway planning and design process consider the functional class as a first step. A determination of functional classification establishes the basic roadway cross-section in terms of lane width, shoulder width, type and width of median area, and other major design features. Design manuals suggest different ranges of these factors for different functional classes. Typical speed limits range between 20 and 35 miles per hour (mph) while the number of lanes varies typically from two to four.

The reference most often used by road designers in the United States during the design of a road project is commonly referred to as the Green Book, published by the American Association of State Highway and Transportation Officials (AASHTO). Its actual title is *A Policy on the Geometric Design of Highways and Streets* and it provides a series of guidelines on geometric design with some amount of flexibility allowed.

The FHWA has adopted applicable parts of the Green Book as the national standard for roads in the National Highway System (NHS) that comprise all the interstates and some other primary routes. The design of roads other than those in the NHS is subject to the standards of the particular state.

“Complete” Streets

Roads should be interconnected, especially in the suburbs where a grid pattern is not present. This allows for more travel route choices and reduces costly widening or changes in other streets. Such an interconnected system improves the value of properties and affords multiple paths of ingress and egress for emergency response and other services.

Recently, the concept of “complete streets” has gained much traction with communities and transportation agencies. A complete street provides for the safe, convenient, and comfortable travel for all modes of travel, including walking, bicycling,

transit vehicles, and automobiles. The streets are safe for people of all physical and cognitive abilities, such as those in wheelchairs or who have low vision. This is accomplished through good design of the street, including interconnected sidewalk and street crossings.

Traffic calming solutions are also applied in street designs, especially on collector and local roads. Such street design is expected to increase the quality of life in a community. It is also argued that incorporating design elements that are supportive of walking, cycling, and public transportation increases the economic and social viability of adjacent land uses. Thus, these treatments enhance the livability (quality of life) and safety of neighborhoods.

Funding for Roads

There are many fund sources for new construction or reconstruction of roads in the United States. One of the major fund sources is the National Highway Performance Program (NHPP), which provides support for the maintenance of and addition to the Interstate highways and National Highway System (NHS). NHS includes all arterials. Funds can be used for construction, repair, and replacement, of roads, bridges, tunnels, bicycle/ pedestrian facilities, safety improvements, etc.

Another major funding support is the Surface Transportation Program (STP). The STP provides funds for projects not in the Interstate System or the National Highway System (NHS). STP-Urban funds are intended to benefit minor arterial and collector roads in urban areas. Funds can be used for a wide range of projects, including roadway widening, roadway reconstruction, and transit projects. The STP-Enhancement Program is designed to help expand transportation choices and enhance the transportation experience.

Federal regulations define categories of eligible activities, including pedestrian and bicycle infrastructure and safety programs, scenic and historic highway programs, landscaping and scenic beautification, historic preservation, and environmental mitigation. Highway Safety Improvement Program (HSIP) funds projects that reduce traffic fatalities and injuries on all public roads.

The Congestion Mitigation and Air Quality (CMAQ) program addresses congestion and air quality problems. Funds must be used for projects that reduce congestion and/or vehicular emissions

and are intended to help achieve the goal of the 1990 Federal Clean Air Act Amendments. Eligible projects include traffic signalization, incident management, and rail/bus transit. In addition, federal and state bridge programs provide funds for bridges on collector roads that meet certain criteria. Municipalities explore innovative financing techniques, including developer-funded road development and general traffic impact fees.

Collision Avoidance Systems, Airplane

Collision avoidance involves prevention of unwanted contact with other planes, obstacles, or the ground. Over half of midair collisions occur within 5 miles of an airport; 96 percent occur below 3,000 feet, and 40 percent occur below 500 feet. Most happen during the day; less than 2 percent occur after sundown. Most are in the traffic pattern, and high-speed head-on collisions account for only 14 percent of midair collisions. Side impact accounts for 39 percent, with 47 percent due to one plane overtaking another. Some routes and major commercial hubs are congested airspace, and

midair collision risk increases with volume of aircraft in finite space. Commercial airlines continue to add new aircraft to an already congested system.

The first layer of accident avoidance is proper operational procedures. Traffic is assigned lanes—a specific airway at a specific altitude for each craft—and air traffic controllers monitor the various craft and lanes to predict and prevent conflicts. Standard distances are 3 to 5 miles laterally and 1,000 feet vertically. Air traffic controllers advise pilots of measures to take as surrounding traffic dictates. When air traffic control (ATC) fails, an airborne collision avoidance system takes over, giving the pilot what it takes to avoid the collision.

Types of collision avoidance systems include airborne radar (available since World War II), but nonmilitary aircraft that routinely have weather radar rarely carry sensitive anticollision radar. An airborne collision avoidance system (ACAS) may be defined as a system on the aircraft working independently of air traffic control and ground-based equipment to warn pilots that other aircraft are in position for a potential collision. The system may, if the danger is imminent, suggest a maneuver to avoid the collision.

ACAS standards are published in the Convention on International Civil Aviation, annex 10, volume IV. As of 2009 only two versions of the Traffic Alert and Collision Avoidance System (TCAS II) met the International Civil Aviation Organization (ICAO) standard.

ACAS differs from the airborne separation assurance system (ASAS) in that ACAS means a short-range system for prevention of metal-to-metal collisions. ASAS pertains to longer range systems to preserve standard en route separation of 5 nautical miles (9.25 kilometers) horizontal and 1,000 feet (305 meters) vertical.

Airborne collision avoidance systems have the goal of providing the pilot adequate information to take appropriate action in a dangerous situation. Current collision avoidance systems offer proximity warning (PW), traffic advisory (TA), and resolution instruction (RI). PW says an aircraft is near, TA says a particular plane is a threat, and RI tells what to do to avoid the threat.

PW devices were used in the early 1950s, but they quickly became inadequate to handle the increased volume and associated increased collision risk. Collision avoidance systems of various sorts were tried

from the 1950s to the mid-1980s, at which time the TCAS became the standard.

In 1956 a Lockheed Constellation and a DC-7 collided in visual flight conditions over the Grand Canyon with a loss of 128 lives. The collision led to demands for modernizing the air traffic control system, producing the current system for preventing midair collisions. After the Grand Canyon collision, in the 1950s and 1960s the FAA allowed various approaches to collision avoidance before settling on the Beacon Collision Avoidance System (BCAS), an airborne transponder system, in 1974. In 1978 over San Diego a Boeing 727 and a Cessna 172, both under radar control, collided and 144 people died. Restrictions on flight in heavy traffic areas were tightened. The San Diego collision of 1978 led to an expansion of the BCAS, renamed TCAS in 1981.

Traffic Alert and Collision Avoidance System

The Traffic Alert and Collision Avoidance System is a means of actively interrogating other transponders and establishing collision avoidance tactics between two affected planes. TCAS is expensive and used mostly by larger airplanes. TCAS works only if both potential colliders have functioning transponders with altitude reporting.

A collision between a DC-9 and a Piper Archer at Cerritos, near Los Angeles, California, on August 31, 1986, killed 82 people in the air and another 15 on the ground, and the National Transportation Safety Board (NTSB) blamed an inadequate air traffic control system. The Cerritos collision of 1986 led to a congressional mandate in 1987 through the Airport and Airway Safety Expansion Act that the Federal Aviation Administration (FAA) require TCAS on all turbine-powered craft equipped with more than 30 passenger seats by 1992. Congress later extended the deadline to 1993.

The first TCAS on commercial planes began flying in 1990. TCAS was at least partially responsible for the drastic reduction of midair collisions, with none in a decade after implementation. In 2003 the TCAS became mandatory worldwide, and in 2005 the coverage was extended to all planes with over 19 seats or a maximum takeoff weight of 5,700 kg. The TCAS is installed on over 25,000 aircraft worldwide. Since implementation of TCAS, midair accidents have diminished to only one every 100 million flight hours. No TCAS-equipped airplane

has been involved in a fatal collision in the United States. In 2006, however, over the Amazon in Brazil, a Boeing 737 collided with an Embraer Legacy 600 business jet. Even TCAS is not 100 percent sure.

It has to be reliable to ensure that pilots do not lose faith in it due to false alarms or, worse, collide due to missed or delayed threat warnings in a high-density, high-speed air traffic system. In 1973 the FAA transponder minimum performance technical orders had errors pertaining to radar beacons and traffic alert and collision avoidance system capability of detecting aircraft transponders. The "terra problem" has persisted, leading FAA to advise manufacturers of transponders to modify their products to allow them to work with newer radars and TCAS systems.

Because the standard remains flawed, the solutions have created different capabilities by make and model of transponder. A proposed modification requiring a transponder to respond to all radars and TCAS will eliminate problems with saturation in high-density areas, eliminate interference with TCAS and ATC radar, and comply with the international standard.

Relatively Inexpensive Systems

The TCAS, a high-end traffic advisory system (TAS), covers 20 miles and is mostly used for business and charter planes, larger than average general aviation planes. TCAS offers suggested avoidance actions, such as climb or descend for example. TCAS was expensive, costing up to \$40,000, and excepting corporation and charter operations, general aviation planes rarely had it, meaning that almost monthly there was a fatal collision involving the smaller planes.

Finally, Cirrus Design Corporation and others began developing lower cost accident avoidance technology for general aviation, at a minimum a passive receiver that allowed a plane transponder to signal its presence and other planes to receive the signal. A system costing around \$1,800 had the capability of detecting craft six miles away and 2,500 feet above or below, but coverage still has blind spots.

The portable collision avoidance system (PCAS) is a cheaper but passive TCAS available for general aviation aircraft. Rather than interrogating other aircraft as TCAS does, PCAS listens to responses from other interrogations. Like TCAS, it depends

on both parties having functioning transponders with altitude reporting.

Better systems, such as the traffic information system (TIS), have data links from the plane transponder to a ground-based radar network that offers data for a 5-mile radius 1,200 feet above or below, but it is limited to congested traffic areas. The traffic advisory system (TAS) provides active searching of airspace for transponder-equipped planes. This technology handles up to 30 planes in a 2-, 6-, or 12-mile radius, 10,000 feet above or below the plane, and it offers audible and visual warnings of aircraft on potential collision courses. TAS systems at this level can be as cheap as \$10,000. TAS and TIS are becoming standard in new general aviation craft, and units for retrofitting older planes are available.

Light Aircraft

Gliders and comparable light aircraft use a lightweight, easy to install, and inexpensive system known as FLARM to broadcast their position and speed over radio. FLARM also listens to other similarly equipped craft and computes short-term conflicts, advising the pilot by sound and sight. FLARM will not warn of obstacles lacking a FLARM device. The FLARM Web site indicates that 17,000 FLARM systems are in use worldwide.

Other Systems

The most costly plane collision was not in the air but on the ground. In 1977 two Boeing 747s collided on the runway at Tenerife, Canary Islands, with a loss of 583 lives. Since 2003 an average of seven runway incursions a year have occurred, and the majority are caused by general aviation craft.

Other systems include a ground proximity warning system available on larger general aviation and civil airliners to track ground elevation below the craft. Terrain Awareness and Warning System tracks potential obstacles such as tall towers or mountains in the flight path. Synthetic vision offers a computer simulation of the environment outside the craft in low or zero visibility conditions. A ground-based obstacle collision avoidance system uses radar on or near the obstacle to detect approaching aircraft and warn them away. Large and sophisticated craft may employ all or some of the systems, whereas a small general aviation craft may have only one.

In the future, automatic dependent surveillance-broadcast (ADS-B) will free aircraft from dependence on ground-based radar, using instead the Global Navigation Satellite System to exchange information with other aircraft and air traffic controllers. Pilots using the new technology will not have the negative effects of topography or distance, but it depends on the other craft being on the same system, so until it is universal it is ineffective. The FAA has not yet determined how to provide all its ground-based controllers the new technology and how to get all airplanes to use the system. A test of ADS-B is under way in Alaska.

One solution under study is a fuzzy-based system that warns of potential midair collisions and takes control of the aircraft if the pilot fails to respond in a timely fashion. The fuzzy system would divert the craft from its pre-established route in bad weather or heavy traffic.

Pilot Awareness

Some small planes rely solely on the pilot's awareness of his environment. Although general aviation (GA) safety in general has improved over time, there is no corresponding decrease in midair collisions. They maintain at a rate of one a month on average, some with single fatalities or none but others with multiple fatalities. GA also have a tendency to collide on the ground because two aircraft are in the same runway space. The solution to this is for the pilot to start watching for other traffic as soon as he starts the engine instead of waiting until he or she has taken off.

In visual conditions the key accident avoidance system is the pilot. Pilots learn during training to keep their eyes on traffic. Pilot awareness is also critical for commercial pilots with all the latest technology. TCAS is merely an advisory system because it cannot incorporate terrain, weather, traffic not online, and air traffic control instructions. Until the plane has the capability for autonomous collision avoidance, the pilot remains obligated to watch for intrusions.

Collision Avoidance Systems, Automobile

As traffic volumes continue to rise in the United States, collision avoidance systems (CAS) have played a large role in reducing the severity of, and in some cases preventing, automobile accidents. These safety systems use radar or cameras to detect an imminent crash.

The risks of traffic accidents are relatively high. The National Highway Traffic Safety Administration estimates that 15 to 20 percent of reported accidents involve rear-end collisions, and that 88 percent of rear-end collisions are caused by drivers not paying proper attention to the road. There are different ways in which these collision avoidance systems improve traffic conditions, including using radar to reduce collisions, detecting slow or stranded vehicles, automatic braking systems, cruise controls, and automated toll collection devices so drivers can avoid stopping at toll booths and creating a dangerous line of traffic. The development of CAS shows a trend in preventing crashes

rather than simply developing stronger car frames, seat belts, and air bags to cope with the problem.

How They Work

Collision avoidance systems have evolved greatly over the years, although in their simplest form, they contain a sensor at the front end of the vehicle that scans the road for obstacles and monitors the distance from obstacles (cars) in front of the driver. Automatic brakes are applied when the system determines the vehicle is in danger of crashing into an object or another vehicle.

The system is switched on under different criteria. Time-to-collision criteria predicts a crash will occur at the current speeds and distances within a certain time interval. For instance, if two cars are traveling and maintain their current speeds, the point at which they will collide is the time-to-collision. Another instance is referred to as the worst-case criterion, which assumes that the vehicle in front of the CAS-equipped vehicle could use its brakes at full capacity at any time, which would then likely cause a crash.

CAS-equipped vehicles use various maneuvers to prevent an accident. Headway distance control warns the driver whenever the vehicle is following the leading car too closely. A hazard warning alerts the driver of an object, whether it is moving or stationary, within its projected path so the driver has ample time to avoid the crash. Lastly, automatic vehicle control takes over a car's brakes and steering and applies them automatically when it feels it is necessary.

When the CAS warning is deployed, the driver is made aware of this in a number of ways. Visual heads-up displays appear on the windshield in the driver's field of view so that their content can be assimilated in conjunction with the driving scene ahead. This is intended to minimize distractions to the driver. Audio and voice signals are considered to be less intrusive while driving than visual heads-up displays and can be heard despite lighting conditions, which can affect visual heads-up signals.

The bases of all collision avoidance systems are divided into three different types: optical techniques, electromagnetic techniques, and acoustic techniques. Optical techniques are dependent upon environmental conditions, and laser radar is costly, although also more effective than passive infrared. The electromagnetic technique is the best for

determining long-distance measurement. Acoustic techniques are best for short-term, relative distance measurements.

Sensors should be able to determine the headway distance, the relative speed between the preceding vehicle or obstacle and the equipped vehicle, or both. Ultrasonic technology operates sensors by measuring the time-to-flight of a short burst of sound energy. The time required for the ultrasonic wave to return from the obstacle it detects determines how far away the vehicle is. The headway distance is calculated by measuring the time between transmitting a pulse and receiving a reflection. Passive infrared sensors measure the thermal energy emitted by objects in the vicinity of the CAS-equipped vehicle. These sensors are not as costly but also cannot detect the distance to an object with accuracy.

Two techniques exist within laser radar: one using a high-power pulsed-beam of infrared light and one where the amplitude of the light is modulated with a sine wave. Frequency modulated continuous wave (FMCW) radar uses modulated high frequencies so that the frequency difference between the reflected and the transmitted signal is proportional to the distance from the object ahead. In addition, the Doppler shift on the reflected signal can be used to determine the relative speed between the vehicle and the object ahead.

Impulse radar uses very short pulses instead of a continuous wave. By using lower frequency electronics, a resolution similar to that of the FMCW radar can be obtained, and at a fraction of the cost. Capacitive sensors are able to detect close objects using the capacitance variations between electrodes excited at low frequencies. Despite their limited range, they are low in cost and immune to external environmental effects. Vision system techniques are based on the use of a video camera and image-processing software.

Effectiveness

Studies show that collision avoidance systems are highly effective, and consumers should consider vehicles equipped with them. An analysis of insurance claims from the Highway Loss Data Institute, an affiliate of the Insurance Institute for Highway Safety, showed that forward-collision warning systems alert the driver if they are approaching traffic ahead at a rate faster than the cars ahead of them. Automatic braking along with adaptive headlights,

which respond to a vehicle's speed and direction of the steering wheel to help direct the lights onto the vehicle's intended path, are proven to be very effective in lowering crash and accident claims.

One feature, however, appeared to have increased the risk of an accident. Lane-departure warnings, which tell drivers when it is unsafe to leave their lane if they are drifting or considering merging, were found to be unsafe and increase the number of injuries. CAS features are beginning to make their way into all new fleets of cars and many lines mandate their use.

Commuter Buses

After decades of decline, the long-distance bus industry reinvented itself into a wide variety of markets in the 1990s, including that of commuter buses. A flexible, reasonably priced, and essential means of getting to work for thousands, commuter buses play an important role in America's transportation grid. Enhanced government safety legislation and private companies like Google and Microsoft

This 45-foot commuter bus taking on passengers at the Marin County Civic Center in San Rafael, California, is equipped with wi-fi Internet, like many newer commuter buses.

are making important impacts on the commuter bus industry, and local and state transit authorities strive to implement, maintain, and improve their systems, encouraging people to park their cars and ride the bus in order to reduce traffic congestion and environmental impact.

Specifications and Operational Characteristics

Transit planning boards work with established definitions of commuter buses and their operating routes. When a transportation board or transit company interested in establishing and operating a commuter bus company conducts planning meetings, it has a specification list for commuter buses and their operations. Also called transit buses, city buses, or public buses, commuter buses include low floor, double-decker, articulated, and midibuses (in between a minibus and a full-size bus).

Generally speaking, commuter buses have large and often multiple doors for boarding and exiting. They have bench or bucket seats with no head

rests and minuscule or no luggage space. There is equipment to verify tickets or accept fares, electronic signs or roll signs to display destinations, and a pull cord or bus stop request button. They also feature a legal standing-passenger capacity. Modern commuter buses also come equipped with amenities that match the interiors of private cars—the chief competitors of transit buses—amenities that include computer hookups, televisions, DVD players, and Internet capabilities.

Commuter bus routes are fixed and operate primarily in one direction during peak periods; routes are limited in length usually between a central business district and suburbs on the outer edge of the district. The routes feature limited stops and uses multiride tickets. The commuter bus service may also include other services featuring a limited route, limited stops, and a cooperative relationship with another method of transportation.

Public transit authorities, municipal bus companies, and private transport companies on a public contract or fully independent basis are all operators of commuter buses. Often, commuter buses are built to third-party specifications. The operating area of a transit bus can also be defined as a geographic metropolitan area and, for capital cost reasons, some regional size operators may use transit buses interchangeably on short urban routes and longer rural routes. Often transit bus operators feature standard transit buses fitted with coach-type seating for longer distance routes. At times, transit buses can be used as express buses on limited stop or nonstop service at peak times over the same distance as the regular route.

Planning and Implementation

In its guidebook *Bus Rapid Transit Service Design Guidelines*, the Santa Clara Valley Transportation Authority (in San Jose, California) identifies some guidelines for establishing a commuter bus operation or bringing an existing one up to standard. Creating and operating a commuter bus operation involves comprehensive planning. The first step is an initial planning study to determine the feasibility and structure and identify the local commitments necessary for funding, implementing and monitoring the new service. This includes conducting market research to estimate ridership and revenue potential. Identifying and designing route alignments is an important selling point, and designing

stations, facilities, and necessary street improvements is an important step as well. Developing an operations plan and implementation schedule is crucial, as is developing a marketing plan and brand management strategy. A transit board needs to determine the length of time the new service will be tested and after that to decide whether to retain, drop, or modify the service.

Performance statistics for evaluation routes and stations include boardings per revenue vehicle hour, a measure of the number of boardings during a specific revenue hour of bus service. This figure reveals how well the commuter bus is utilized and indicates whether the commuter bus level of service is appropriate and how well operating resources are used. The number of daily boardings versus the total route length or network is compared to assess whether a route is effectively designed, taking its length and extraneous destinations into consideration. The figures can be used to identify route segments with higher demand, allowing the transit authority to tailor service and capacity.

If a commuter bus service already exists, it is necessary to determine whether existing services meet established service standards. If existing services do not meet established service standards, an improvement plan must be submitted.

New Legislation for Commuter Bus Safety

The federal government recently updated safety regulations for commuter buses by giving the Federal Transit Administration (FTA) authority to enforce a new, comprehensive framework to oversee the safety of millions of passengers riding public transportation every day.

On July 6, 2012, President Barack Obama signed Moving Ahead for Progress in the 21st Century (MAP-21), reauthorizing surface transportation programs through 2014. Effective October 1, 2012, MAP-21 reauthorizes surface transportation programs and amends the federal Transit Laws codified in 49 U.S.C. Chapter 53. The legislation includes many of the new authorities included in the administration's original proposal and also includes important safety provisions for bus-only operators.

Under MAP-21, backed by \$25 million a year in new funding for safety and inspection-related training, transit agencies may discover risks they did not know were as serious as they are, according

to government officials. The FTA will implement MAP-21 in consultation with the transit community, the Transit Rail Advisory Committee for Safety, safety experts from the transit industry, transportation labor groups, and academic institutions around the country. The new standards will replace existing state laws.

In Chicago, MAP-21 will fund new oversight activities designed to provide a close look at issues ranging from vehicle maintenance and track inspections to operations and action plans in response to emergencies. According to Chicago Transit Authority (CTA) officials, the need for tighter supervision is especially needed in the Chicago area because much of the transit infrastructure does not meet state-of-good-repair standards. Until MAP-21, commuters using a combination of the CTA, Metra, Pace, and the South Shore Line and transferring from one system to the other were not covered by a consistent safety net.

Regional, state, and the federal governments can cooperate to ensure the success of commuter buses through existing programs, by revising laws and by funding policies. In 2008, the Metropolitan Transit Authority in New York introduced Select Bus Service System (SBS), featuring more frequent service, especially designed buses with flashing lights, coordinated traffic signs, and an off-board fare-collection system. The federal and state governments cooperated with the MTA to create the system, which operates successfully and with increased ridership.

The Maryland Transit Administration (MTA) sponsors Commuter Choice Maryland, an incentive program that encourages Maryland workers to ride commuter buses or vanpools instead of driving to work. Commuter Choice offers employers monthly pass options to ride MTA local and commuter buses, light rail, metro subway, and MARC Train for reduced fares.

Private Commuter Buses

Among their employee perks, employers like Google, Yahoo!, Genentech, Cisco, eBay, and other technology companies offer private commuter buses that pick up employees close to home and speed them to work, then back home again when the workday ends. The San Francisco County Transportation Authority estimates these luxury eco-buses eliminate about 327,000 solo vehicle round

trips a year from Bay Area roadways, reducing CO₂ and non-CO₂ emissions. Private commuter buses also boost neighbor businesses when commuters shop local stores.

Employers like Google benefit because the private commuter buses help them meet city transportation demand management (TDM) requirements and reduce the company's environmental impact. The buses are a valuable recruiting tool and they increase employee productivity and decrease parking demand.

Not everyone approved of the private commuter buses. Some people complained about the large buses roaring through their neighborhoods and idling on residential streets or that the private commuter buses conflicted with city bus schedules when they loaded passengers or idled at the same bus stops.

Krute Singa and Jean-David Margulici, researchers at the California Center for Innovative Transportation (CCIT), conducted a study of the effects of the luxury commuter shuttles on employees, employers, and residents and on public transportation. One of the conclusions they reached in their 45-page report, *Privately-Provided Commuter Bus Services: Role in the San Francisco Bay Area Regional Transportation Network*, was that public transit agencies and private employers sponsoring commuter buses could work together. They also suggested that regional transportation agencies could formally integrate private commuter buses into their planning. They said that states could promote ride sharing, transit, and alternative modes of transportation, and regional, state, and federal governments could encourage the success of private commuter buses through existing programs, revising laws, and making funding available.

Seattle's Microsoft Corporation took a different approach from that of the San Francisco Bay Area. Instead of sending their private employer buses into residential streets without coordinating with the city, Microsoft's transportation staff met with the King County Metro Transit board and they worked out a system whereby Microsoft's shuttle service, Microsoft Connector, augmented service for employees when it was not available through public transit.

The Microsoft Connector does not compete with King County Metro, which operates a diverse fleet of buses, electric trolleys, streetcars,

paratransit vans, and vanpool programs, but instead the Metro acts as mobility manager, filling transportation gaps and providing a cohesive transportation network. The Microsoft Connector is allowed to use a bay at Metro's bus transit center but is prohibited from using on-street transit stops. Microsoft worked with local churches and businesses to establish stops in white curb zones and parking lots. It averages over 3,400 riders a day over 55 routes, or just under 1 percent of Metro's daily boardings.

The study also suggests that employer commuter buses should receive funding using the action of Massachusetts Bay Transportation Authority (MBTA), as an example. The MBTA acknowledged that it could not provide service to certain outlying areas, but it paid a private company to provide the service, finding it more cost effective to fund private operators than to let them go out of business and be required to provide the funding and service itself.

Commuter Paradox

The paradox in the commuter paradox refers to the perception that commutes are getting longer (predominantly in time) when that is not necessarily true in reality. For the most part, commuting times in the United States have stayed about the same over the last 30 years. Comparing the United States to the rest of the developed world, the commuting times of those who are employed full-time in the United States are currently not among the longest in developed countries. That distinction belongs to first, South Africa (56 minutes per day), second, Korea (55 minutes per day), and third, Turkey/Japan (48 minutes per day). On the contrary, commuting times in the United States are among the shortest in the world: (1) Ireland (26 minutes per day), (2) Denmark (27 minutes per day), and (3) Sweden/United States (28 minutes per day).

To what, then, can the perception of longer commutes be attributed? The usual culprit is congestion. Indeed, anecdotal and empirical evidence highlight just how ubiquitous congestion has become in metropolitan areas across the United States. What was once a phenomenon that negatively impacted the all-important work-life balance of large-sized metropolitan-area dwellers has come to visit those living in medium- and small-sized metropolitan areas as well. Internationally, congestion is becoming more readily identified as adding costs to the movement of people as well as of goods and services.

If congestion is indeed problematic the world over, then why hasn't it had a direct, negative effect on commuting times in the United States (by making them longer)? In addition, is it reasonable to expect that the commuter paradox won't become a reality in the future? Both of these issues are taken up in the following sections.

Congestion and Commuting Times

One trend that directly impacts congestion, but not necessarily average commuting times, is the distribution of trips. Trips are typically broken down into the following categories: work, shopping, recreation, and social. While work trips continue to be important, it is the increase in the numbers of non-work trips that has had an impact on congestion, especially during nonpeak hours of the day in the United States. The growth in nonwork trips and trip

chaining wherein one trip encompasses any combination of these different trip types has had a direct impact on congestion.

Another trend that has directly impacted congestion is the increase in the number of vehicles per household. Over time in the United States, the number of zero-vehicle households has decreased and the average number of private vehicles (cars, pickup trucks, vans, and sport utility vehicles) per household has increased. This increase in vehicle availability is a sign of several realities in the U.S. labor market.

First, the dual-income household is much more common than in the past and coincides with greater female labor force participation rates. It is also true that the recent economic recession has made it a necessity for both wage earners to have access to a vehicle in order to cobble together several part-time jobs and so maintain household income levels.

Second, because most commutes today are between home and work locations that are both in the suburbs where public transportation is often not available, the private vehicle is often the only viable mode choice for commuters. While there is some evidence that the dispersion of jobs away from more central locations in metropolitan areas across the United States has abated due to the Great Recession, the decentralization of employment to the suburbs has had a direct effect on congestion.

Commuter Paradox and the Future

One explanation for the stability of commuting times in the United States is that firms and households are synchronously adjusting their locations, typically on the periphery of metropolitan areas across the United States, to accommodate greater congestion. These rational actions on the part of commuters to adapt to the decentralization of employment and the most negative effects of congestion help understand the phenomenon known as the commuter paradox.

To follow this explanation to its logical conclusion then, any disruption in the ability or willingness of commuters to continue to adjust their home locations to account for congestion will lead to longer average commutes. Given the brief window of time since the Great Recession, which has had a direct effect on the decentralization of

employment and the ability of homeowners to easily sell and buy within their own real estate markets (because many homeowners now owe more on their mortgages than their homes are worth), it is too soon to empirically verify the rational locator hypothesis. However, given the ubiquity of congestion and the importance of residential real estate to the general state of the U.S. economy, the commuter paradox will continue to be an important topical area of research in transportation and regional development.

Commuter Rail

Planners view commuter rail as a means of managing urban sprawl, stimulating economic development, and reducing the environmental impacts of transportation. Commuter rail systems, which use shared rights-of-way to connect suburban hubs

with downtown urban centers, have a large impact on the way people and freight move through many of the larger urbanized areas in the United States. Currently, there are 24 commuter rail systems operating in 29 major U.S. metropolitan areas.

Commuter rail, sometimes called regional rail or suburban rail, is uniquely situated between standard passenger rail and intra-urban rail transit. Commuter rail systems operate frequent and regular services that are scheduled around traditional peak commuting hours. These services are designed to move commuters within the greater metropolitan area and establish a connection between suburban communities and the city center, although a few systems connect adjacent metro areas (such as Dallas–Ft. Worth or Washington, D.C.–Baltimore). Commuter rail systems operate on shared track infrastructure with freight rail carriers and Amtrak passenger rail. These shared corridors usually range between 30 and 200 miles of track, although the very largest systems in the country have up to several hundred miles of track.

Commuter rail systems can be classified using a "legacy" or "new start" dichotomy. There are nine legacy rail systems and 17 new start systems operating in the United States. Legacy systems were previously operated as private commuter rail services but were acquired by public transit agencies after World War II. New start systems are more recently developed commuter rail services established by public transit agencies after 1980.

New start commuter rail systems have been established by public transit agencies using start-up funding from Federal Transit Administration (FTA) grants designed for establishing new fixed guideway transit systems—including commuter rail. While municipal transit authorities acquired legacy systems as a turnkey operation, complete with right-of-way and rolling stock, new start systems have had to negotiate the terms of establishing new shared corridors with freight rail carriers that own the track infrastructure. Some new start commuter rail systems subcontract the day-to-day operations to private companies, such as Herzog Transit Services or Veolia Transportation, but these systems are still under the governance of local public transit agencies.

Based on an urban area's existing infrastructure and previous commuter services, there are three scenarios for establishing new start systems. The

most common scenario is commuter rail being established from the ground up in areas that have recently begun to rapidly urbanize. These systems are designed and built in cities with no previous history of commuter rail service.

The second scenario is the re-establishment of long-dormant commuter lines that were not acquired by public transit agencies after their discontinuance. Some large urban centers had commuter services operating prior to 1950 but whose services were abandoned for several decades before the creation of the current commuter rail service.

The third scenario is the modification of existing passenger rail service to provide commuter rail services. These new start systems expand the capacity of existing Amtrak passenger rail services, allowing a set of commuter express trains to run hourly during peak commuting hours.

Regardless of the start-up scenario, the biggest challenge in planning a new start commuter rail system is the acquisition of a rail corridor from the private freight carrier that owns the track infrastructure. There are three strategies of corridor right-of-way acquisition: (1) purchasing the track infrastructure outright, (2) purchasing an easement along the freight carrier corridor, or (3) leasing a specific number of daily commuter trips on the corridor. While the initial investment is greater, purchasing track infrastructure allows public transit agencies to control the dispatching of commuter and freight trains. This allows commuter rail systems to better control scheduling and ensure higher on-time rates.

Recent increases in commuter rail trips indicate that commuter rail service will continue to grow nationally as more new start commuter rail systems are being established in cities and as ridership grows on legacy systems. Between 1997 and 2007, commuter rail added 100 million additional riders—a 28 percent increase in national ridership. This is the first sustained increase in rail ridership since 1945. Long-term rail ridership had been in a state of decline since World War II, as personal automobile ownership became more commonplace.

In 1962, President John F. Kennedy delivered a special message to Congress calling for planning efforts and capital assistance for U.S. urban mass transit. Departing from the interstate highway-focused planning convention of the time, the

Kennedy administration also asked Congress to conduct a comprehensive study of U.S. intercity transit policy and rights-of-way to facilitate the creation of a national multimodal transit system. This resulted in an effort to address the problem of deteriorating commuter rail service by establishing the Urban Mass Transit Administration (UMTA). As a predecessor to the Federal Transit Administration, the UMTA began providing capital grants for metropolitan areas with a comprehensive transit plan.

The Rail Passenger Service Act of 1970 enabled the federal government to relieve freight rail lines of their common carriage responsibilities, allowing these companies to end their intercity passenger services. When these passenger rail carriers relinquished their passenger services to Amtrak, many commuter rail services were discontinued. Conrail began privately operating some of these

Drivers and bicycle riders wait for a Massachusetts Bay Transportation Authority Commuter Rail train to pass in Concord, Massachusetts, in 2010. Between 1997 and 2007, U.S. national commuter rail ridership increased 28 percent.

commuter systems until the early 1980s, when the company was on the verge of bankruptcy. As part of the Northeast Rail Service Act of 1981 (NERSA), Conrail was released from its commuter rail carrier obligations, which allowed the five Conrail regional commuter rail systems to be purchased by state and municipal public transit agencies in 1983 and 1984.

Commuter Rail Systems

Commuter trains are a type of passenger rail intended to be used daily as part of individuals' daily commute. Commuter trains are set apart from long-range passenger rail in that they provide service between city centers and commuter residential areas. In the United States, both commuter and long-range passenger rail share rail space with freight trains; prominent American rail systems include the New York subway system; San Francisco's Bay Area Rapid Transit (BART), Washington D.C.'s Metro, and the Chicago "El" train.

International commuter rail systems include the London tube system; the iZBAN in Ismir, Turkey; and the S-Bahn in the Ruhr region of Germany.

Commuter rail development is by no means uniformly developed around the globe. Asia boasts some of the most advanced commuter rail systems, with notable networks found in India and Japan. European systems, while not necessarily as technologically advanced as their Asian counterparts, are impressive in their accessibility, with most major metropolitan areas served by some sort of commuter rail. Compared to global counterparts, commuter rail lines are limited in North America and South America, with even more limited options in Africa.

Commuter Rail in the United States

Due to historical factors and business interests, freight trains are given priority on American rail lines, with both long-range and commuter passenger trains taking secondary priority. The fact that commuter trains play a vital role in the daily lives of millions of Americans have led many to question if the American commuter rail system is in need of an overhaul. Such expansion raises at least three key questions. First, can commuter rail systems provide an environmentally sustainable alternative to automotive commuter systems? Second, would commuter rail systems alleviate congestion issues experienced in many American cities? Finally, would viable commuter rail systems provide sufficiently appealing alternatives to justify the capital expenditure necessary to put them in place?

Only 6 percent of the 380 metropolitan areas in the United States host functioning rail systems—a total of 24 functioning rail systems nationwide. The largest and most developed rail system in the United States exists in the Northeast Megalopolis (including the Boston, New York City, Philadelphia, and Washington, D.C., metropolitan areas); two-thirds of U.S. rail commuters live in New York City.

The rail systems that occupy the Northeast Megalopolis are connected by the National Passenger Railroad Corporation, known as Amtrak; however, a minority of Amtrak's activity focuses on longer distance travel. Amtrak operates on 21,000 route miles in 46 states, the District of Columbia, and three Canadian provinces. Of those 21,000 route miles, only 363 miles reside in the Northeast Corridor between Boston and Washington, D.C.

As mentioned above, the historic factors that limited rail systems in the United States largely contained those systems to the northeast.

However, the west is not completely without rail systems. The most prominent of those Pacific Coast rail systems is the Bay Area Rapid Transit (BART) system. The first track of this system was laid in 1946; its initial development was driven largely by postwar migration to the area and a corresponding lack of motorways in the area. In fact, counter to the anti-rail trend in the rest of the country, BART was actually developed in order to avoid total dependence on automobiles.

Potential Solutions Provided

Many argue that the implementation of commuter rail systems where they do not yet exist could be greatly beneficial. One such benefit would be more environmentally friendly transportation for America's commuters. Currently, most rail systems in the United States draw their power from the same sources as residential areas; thus they are largely reliant on coal and other fossil fuels. However, once the electrical infrastructure is converted to more sustainable energy sources (such as solar, wind, hydrothermal, etc.), rail systems will likely utilize cleaner energy sources. Additionally, expanded rail systems will allow commuters to give up driving if they wish. If enough commuters transition from their automotive commute to a rail commute, automobile emissions could be reduced significantly.

The argument has also been made that the commuter infrastructure of our nation's cities must be improved to cope with increasingly populated cities. Cities with large populations and limited public transit systems, such as Los Angeles, are already suffering from almost intolerable levels of automotive gridlock. Social scientists are already predicting that the urban sprawl of the last few decades may be receding to be replaced with more centralized, compact cities. Such cities would not be conducive to universal automobile ownership and thus likely would require advanced commuter rail systems.

As appealing as improvements to our rail infrastructure may seem, economic viability will be a major consideration in determining if each given project goes forward. Opponents of rail projects have argued that they are simply too expensive a venture and that the risk is too great that the commuting public will not embrace rail systems. It is not uncommon for states or cities to own rail systems, and most private rail companies receive

some sort of subsidy from the government. For this reason, expansion projects often become embroiled not only in logistical delays but also in political disputes.

Where Now?

There are currently over 25 rail projects proposed or under construction in metro areas across the United States. These include both the expansion of existing systems and the installation of entirely new rail systems. These projects are taking place in Pittsburgh, Austin, Detroit, Milwaukee, and San Francisco, among other cities. If this generation of commuter rail projects moves forward as predicted, we shall see whether environmental and commuting problems if these metro areas are resolved, and whether these cities prosper financially as a result. If so, we may yet see widespread commuter rail in the United States.

Commuting

Daily commuting, the movement between place of residence and place of work, is a common phenomenon in the modern-day world since the arrival of motorized transportation (electric streetcar, rail,

car, etc.) in late 19th century. Before this time most workers lived less than a 30-minute walk from their work. Approximately 128.3 million U.S. workers (93 percent) commute to work every day and spend on average more time commuting than on vacation each year.

Even though the share of daily travel composed of commute trips has been in decline since 1995, this is not the result of diminishing work travel. Rather, it is due to the dramatic growth of trips in other non-work-related activities. Commuting constitutes less than 20 percent of all trips taken daily, but it is a vital activity for millions of American households during rush hours in the morning and evening and hence plays a unique role in the American transportation system and society.

Unlike many other important American social issues, commuting often dominates public discussion about transportation because it takes place during the most congested times of the day and is experienced by millions of American workers of all income levels, either directly or indirectly. These experiences can be referred to as time and money wasted and boredom with the journey, congestion and mobility, energy and pollution, and so forth, all with negative outcomes for communities, along with less time for family life, stress, and other personal health issues.

According to a Texas Transportation Institute mobility report in 2011, American commuters spent an extra 38 hours traveling, up from 16 hours in 1982, and wasted 19 gallons of fuel—a week's worth of fuel for the average U.S. driver—up from 8 gallons in 1982.

Table 1 Average commute times in the United States and Europe

Country	Average Commute Time
United States	26 minutes
Italy	23 minutes
Spain	33 minutes
France	36 minutes
European Union average	38 minutes
Netherlands	43 minutes
Germany	44 minutes
United Kingdom	45 minutes

U.S. Commuting

Americans are spending more time commuting than they did 40 years ago. Based on the 2006–10 American Community Survey, the average one-way commute time was 21.7 minutes in 1980, the first time the census collected commute data. Since then, average one-way commute time increased from 22.4 minutes in 1990 to 25.5 minutes in 2000, and declined only slightly to 25.1 minutes in 2009. Today the average American commutes a little less than 26 minutes and 16 miles each way.

Compared to many European countries, average commutes for U.S. workers are shorter (see Table 1) because of the dominant use of the private automobile for travel. The average travel time for workers who commute by public transportation is higher than that of workers who use other modes. However, the share of “long commuters,” those who commute 60 minutes or longer each way, is on the rise. In 2011, 10.8 million or 8.1 percent of U.S. workers were long commuters, up from 8 percent in 2000. Of all long commuters, “extreme commuters” who commute 90 minutes or more to work each way are also on the rise.

The U.S. 2000 census identified 2.8 percent of commuters as extreme commuters, which is up from 1.5 percent extreme commuters in 1990. However, this proportion has fluctuated since then, and it reached 2.5 percent in 2011. The recent census also classified 3.3 million (3.15 percent) U.S. workers as “stretch commuters” or “long-distance commuters,” who commute 50 miles each way; and 600,000 U.S. workers (0.82 percent) as “mega-commuters,” traveling 90 minutes or more and at least 50 miles to work each way. Moreover, the number of people who start a commuting trip very early (5 A.M. to 6 A.M.) to avoid traffic jams on highways that typically occur during peak commuting hours (6 A.M.–10 A.M.) rose significantly from 6.4 percent in 1990 to 7.6 percent in 2000 and up to 8.6 percent in 2009.

The car is by far the most commonly used mode of transportation for commuting to work in the United States compared to Europe and Japan and other east Asian countries (see Table 2). In addition, American commuters also prefer driving solo to work. Based on the 2006–10 American Community Survey, the majority of American commuters, about 76.1 percent, usually get to their employment locations by driving alone, compared to 64.4 percent in 1980 and 60.0 percent in 1960.

Changes in family structure, such as dual-earner versus traditional households, and vehicle availability primarily affected mode choices since the 1980s. Only 12.2 percent of American commuters carpooled, a decline from 19.7 percent in 1980 but steady since 2000. In contrast, a small percentage of American commuters (5 percent) use public transit for commuting purpose compared to 49 percent in Europe and 56.4 percent in Japan (see Table 2). However, public transit use for commuting is on the rise in the United States after decades of decline.

Europeans are by far more likely to walk to work compared to any other region. Only 3.3 percent of American commuters walked, but this number is rising slowly after decades of decline. Even though bike commuters represent only a small share of commuters in United States, about 0.4 percent compared to Japan and Europe, their number has been steadily rising since 2000.

Sociodemographic Characteristics

Women have significantly different commute patterns than men. Women, for example, tend to have shorter commutes than men but tend to link with other trips. The average one-way commute time for men is 35 minutes versus 20 minutes for women. More than 50 percent of females in the United States commute less than 20 minutes compared to 43 percent of men. In contrast, 9 percent of males are “long commuters” versus 6 percent of females. Similarly, megacommuters are more likely to be older, married, make a higher salary, and have a spouse who does not work. Of the total mega-commuters, 75.4 percent were male and 24.6 percent were women. Mega-commuters were also more likely to depart for work before 6 A.M. Metro areas

with large populations tend to attract large flows of mega-commuters.

Racial and ethnic variation in commuting time and mode choices is also significant in the United States. The non-Hispanic white population has the highest share of less than 20 minutes (48 percent) and the lowest share (7.3 percent) of 60 minutes or above commutes. In contrast, African American (10.62 percent) and Asian populations (10.29 percent) have the highest share of 60 minutes or above commute and the lowest share of less than 20 minute commutes (38.95 percent and 38.58 percent, respectively). By far, more white workers (84.5 percent) drove alone to work than any other racial or ethnic group. The percentage of Hispanic and non-Hispanic Asian workers who drove to work alone did not exceed 70 percent. Notably, Hispanic workers had the highest rate of carpooling to work (16.4 percent). Non-Hispanic Black workers had the highest proportion (11.5 percent) of transit use for commuting in contrast to only 3.2 percent of non-Hispanic white workers.

Similarly, there are significant variations in commute time and mode choice among native-born and foreign-born populations. Commute time is by far longer, with 28.1 minutes for foreign-born workers, compared with 24.9 minutes for native-born workers. Hispanic workers had the longest mean travel time when carpooling (29 minutes) and the shortest time for public transportation usage (46 minutes). Public transit and carpool users also double among the foreign-born population compared to the native-born population (10.8 percent compared to 4.1 percent, respectively). The biggest gap is in bus usage. Black commuters spend an extra 66 hours a year waiting, riding, and transferring than white bus riders.

Table 2 Mode of transportation used for commuting

Region	Mode of Transportation (percent of commuters)			
	Car	Transit	Walk	Bicycle
United States	86.1	5.0	3.3	.4
Europe	26.7	48.7	15.0	5.9
Japan	16.8	56.4	6.8	13.4
Other East Asian	14.6	68.9	10.1	.8

Increasing Commutes

The topic of lengthening commutes has naturally attracted attention across the disciplines that deal with its effect on human aspects of everyday life. Among researchers on this topic, geographers, planners, transport engineers, economist, sociologists, and psychologists are recognizable. They have identified a number of reasons for the lengthening commute in the United States:

Suburbanization and low-density development is conducive to a long commute due to job–housing imbalance/mismatch. Job–housing imbalance occurs when the number of workers who can be housed in an area differs substantially from the number of jobs there. Job–housing mismatch occurs when price or other characteristics of the housing in an area are unsuitable (either too expensive or lower quality neighborhoods) for the earning potential of available jobs. Researchers have argued that lack of affordable housing near job locations and racial discrimination and other exclusionary practices in suburban locations have displaced workers to residential communities far from their jobs.

Changes in workforce: A majority of American households are now dual earner, compared to the 1960s. Location decisions for dual-earner households are complex, and the job–housing balance is unattainable for them since living near one household member’s job may mean living far from the other’s. Therefore, it has been suggested that continuing growth of dual-earner families could be an increasingly important factor in increasing commuting time in metropolitan areas.

Complete Streets

For more than half a century, the personal automobile has been king of the road in terms of transportation planning and funding in the United States. More recently, consideration has been given to the need to accommodate all modes of transportation, not just the motor vehicle. By designing and retrofitting streets, the complete streets movement takes into account the needs of all users. This thinking represents a trend away from equating transportation with mobility and toward accessibility. Mobility means fast, convenient travel. Accessibility focuses on the ability to reach desired destinations safely.

By according consideration to pedestrians, bicyclists, and users of public transit, a complete street is one that may include wide sidewalks, bike lanes, bus lanes, and a variety of traffic-calming devices such as raised crosswalks and pedestrian signals, as well as other features that demonstrate concern for the nonmotorist. The complete streets movement upends the prevailing thought by first considering the most vulnerable of users, the pedestrian. Bicyclists and mass transit users are then accommodated, only after which is automobile mobility

addressed. Ultimately, the complete streets ideal is to provide transportation options that may ultimately transform the community at large.

Though a relatively nascent movement, complete streets policies have already been adopted or received commitment to do so by more than 200 jurisdictions nationwide, including statewide laws or ordinances in 15 states. The foundation of the movement is frequently traced to the 1991 Intermodal Surface Transportation Efficiency Act (ISTEA), which dramatically increased the amount of federal funding available for pedestrian and bicycle facilities.

In 1998, the Transportation Equity Act for the 21st Century (TEA-21) further augmented federal funds for nonmotorized spending. By 2003, more than \$1.4 billion was spent on bicycle/pedestrian projects under TEA-21 funding. The most recent federal transportation legislation, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) was

enacted in 2005 and afforded an even more dramatic upsurge in potential federal funding on bicycling and walking. Set to expire in 2009, SAFETEA-LU was extended through 2012 and has been recommended by the U.S. secretary of transportation to receive additional funding by Congress in 2013.

Determination of how best to allocate the funds is left to metropolitan planning organizations (MPOs) in metropolitan areas with populations greater than 50,000, and by state departments of transportation (DOTs) for smaller metro areas and nonmetro areas. As Congress has not mandated that the money be spent on bicycle or pedestrian infrastructure, there may be considerable variation in how transportation funds are allocated.

Despite this variation, nonmotorized transportation options have received augmented funding due to growing awareness of the many tangible benefits of complete streets. Increased safety, improved health, and reduced traffic congestion, as well as increased social capital, economic opportunity,

This Vancouver, Canada, street design incorporates a physically separated two-way bike lane and wide sidewalks, allowing a large number of people to use of modes of travel besides automobiles. Improvements in bicycling, walking, and mass transit facilities as promoted by the complete streets movement can improve neighborhood quality of life as well as reduce fuel consumption and waste. It is estimated that increasing U.S. bicycle trips to 1.5 percent, up from 1 percent, could save 500 millions gallons of gasoline a year.

land values, and overall livability, are all linked to complete streets. The National Household Transportation Survey has found that fully half of all trips that occur in the United States are 3 miles or less. With options of multimodal travel, these trips may readily and even preferably be made via walking, bicycle, or mass transit.

In settings with incomplete streets, the automobile remains the primary mode of travel due to safety issues or a lack of alternatives. Complete street communities can help reduce automobile travel and increase movement via other options. Small changes, made collectively in communities throughout the United States, can net a profound impact. As noted by Dan Burden and Todd Litman, merely increasing trips made by bicycle from 1 percent to 1.5 percent of all trips in the United States would save nearly 500 million gallons of gasoline per year. Similarly, current use of mass transit is already helping save just under 4 million gallons of gasoline every day.

Fewer motor vehicle trips not only lessen gasoline consumption and dependence on oil, but also lead to cleaner air by reducing greenhouse gas emissions. Complete streets also bring social and economic benefits to communities. Work to develop new infrastructure or upgrade existing streets is part of every community's yearly budget. This work, which would necessarily have taken place anyway, can be designed to follow the complete streets model. The creation of complete streets is therefore not truly a new or added expense. On the contrary, fewer cars on the road means infrastructure savings, while improvements in walking, bicycling, and mass transit facilities can contribute to increased tourism, retail sales, and land values. Moreover, complete streets add to the more intangible concept of livability. Feelings of safety, environmental quality, social equity, and economic opportunity all contribute to a sense of place and quality of life that benefit from the complete streets model. People who are given an opportunity to walk are more likely to meet recommended physical activity levels as well as to improve their social connections and enjoy a heightened sense of neighborliness. As a result, complete streets are about much more than just infrastructure.

Despite the unquestioned benefits of complete streets, the movement can experience obstacles in implementation. Transportation policies in many

communities still favor mobility over accessibility, while a lack of integration can limit the success of complete streets. Widening a sidewalk or adding a bicycle lane is insufficient. Rather, the complete streets efforts must be tied to larger land use and transportation planning efforts.

The National Complete Streets Coalition has identified 10 essential elements of an ideal comprehensive complete streets policy as one that includes a vision for how and why the community wants complete streets; specifies that "all users" includes pedestrians, bicyclists, transit users, and motorists of all ages and abilities; encourages streets to be connected; is adoptable by all relevant agencies to include all roads; applies to new, maintenance, and resurfacing projects; clearly explains any exceptions; directs the use of the latest design standards while also recognizing the need for flexibility; focuses on the positive community impact as a result of complete streets; establishes performance standards with measurable outcomes; and includes specific next steps for implementing the policy. This 10-step program, in tandem with community support and incorporation into relevant land use and transportation policies, offers a blueprint for successful complete streets development and implementation.

Congestion Mitigation and Air Quality Program

The Congestion Mitigation and Air Quality Improvement (CMAQ) Program is landmark legislation passed in the first months of the Clinton Administration as part of its commitment to assist metropolitan areas that were routinely subjected to air quality warnings due to poorly-managed high-volume traffic congestion.

It remains the first and only federally funded program aimed specifically at addressing air quality through surface transportation improvements. The program was part of the Clinton Administration's overall vision of responsible, cost-effective environmental policy that could go hand in hand with economic development.

Congestion mitigation has long been a critical element in transportation planning. Indeed, the evolution of the American nation was tied to surface transportation management. Unprecedented development over the past century and half of an increasingly sophisticated network of surface transportation systems has been intrinsic not only to uniting the country and building a national economy but also to sustaining the spirit of mobility that has become an essential element of a restless nation proud of its pioneering spirit.

Surface transportation evolved within decades from hastily fashioned trails west and south to a system of maintained roadways, then to the introduction of a massive system of rail lines. Within a generation came the automobile, streets and highways, and an increasingly complex system of interstate freeways. Thus, congestion mitigation has long factored in transportation planning.

Unlike other urban and industrial development—such as housing or building construction—transportation systems have more widespread and longer lasting impacts on their environments. Roads and highways are around for generations. It is far easier, after all, to raze a factory and replace it with one more efficient than it is to remove an entire highway system. However, in the 1970s environmental scientists, climatologists, and mechanical engineers first began gathering hard data on ambient air quality and the growing problem of air pollution from fossil fuel vehicles—even as the number of those vehicles skyrocketed.

From the beginning, the goal in the government's endeavor to manage vehicular congestion was both practical and pragmatic. With the cooperation of congressional oversight committees, blue-ribbon committees made up of academics and field specialists, as well as federal agencies responsible for transportation and highway maintenance, the emerging policy focused on developing realistic, short-term goals that would have immediate and measurable impacts on air pollution, particularly in urban areas that consistently failed to attain federal minimum air quality standards.

By the early 1990s, in the closing months of the first Bush administration, principal goals had been outlined to reduce congestion and improve air quality: (1) reduce fossil fuel emissions, (2) encourage multipassenger and/or public transportation systems to reduce traffic volume, (3) step up vehicle inspection and maintenance, and (4) develop workable alternatives to vehicular transportation, most notably bicycling and pedestrian programs.

The sweeping Clean Air Act Amendments (CAAA) passed by Congress in 1990 had begun to tackle the problem of urban air pollution by imposing hard deadlines for cities to meet nationally set air quality standards. So-called nonattainment areas were most often in large cities with sprawling highway systems built during the 1950s and 1960s and, therefore, not up to the high capacity demands of late 20th-century traffic. Determined to bring those zones into compliance, the Federal Highway Administration, the Federal Transportation Administration, and the Environmental Protection Agency considered stringent compliance requirements the best way to mitigate urban traffic congestion. Within a year of the passage of the CAA amendments, Congress established the CMAQ program to fund project proposals for initiatives that addressed surface transportation problems.

Its passage attracted little national attention, yet it has become something of a model for how the federal government can actually work effectively through small and targeted government initiatives producing measurable and specific results. Initially, the program was given a six-year charter and a \$6 billion dollar budget. One of the long-standing problems that the new program was designed to eliminate was simply the unworkable centralized nature of so much urban traffic planning, which too often exacerbated rather than relieved clogged

traffic conditions. Often local agencies simply lacked the broad-based funding necessary to seriously tackle vehicular congestion. By placing the evaluation of potential programs in the hands of a complex of federal agencies, the CMAQ program sought to encourage immediate, practical, and workable solutions to local problems.

The program met with great success and was reauthorized in 1998 under the Transportation Equity Act for the Twenty-First Century (TEA-21); its budget was increased to \$8 billion. Despite the changeover to a Republican administration and despite the general reduction in federal spending and the economic downturn in the aftermath of the September 11, 2001, terrorist attacks, the program was again reauthorized in 2005 as part of the Safe, Accountable, Flexible, and Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU); and, under the Obama administration, most recently in July 2012, in the Moving Ahead for Progress in the Twenty-First Century Act (MAP-21).

The high degree of bipartisan support indicates both the level of the federal commitment to bringing areas into air quality compliance and the sense of urgency surrounding the potential consequences of climate change. It is difficult to overestimate the achievement of the CMAQ program—to date, through both Republican and Democratic administrations, through economic boom times and economic downturns, it has funded more than 29,000 transportation/environmental projects for more than 23 states and has overseen the distribution of more than \$30 billion.

Under the program, proposals may be submitted by local governments, state governments, public transit authorities, public transportation management administrations, and even public and private corporations, according to an elaborate formula that takes into account three critical factors: population density, ozone and carbon monoxide measurements as well as particulate matter, and most important, vehicle distribution and concentration.

Evaluating the worth of project submissions and deciding on what projects receive funding must take into consideration a number of interrelated concerns, including transportation demand analysis, long-term urban planning, air quality monitoring, human exposure assessment, population demographics, emissions regulations, vehicle engineering, fossil fuel supplies and distribution,

ecological balance, the viability of the industrial superstructure, local environmental planning, short- and long-term economic development initiatives, as well as the complex interplay between local and state politics.

The broad intention of congestion mitigation is to decrease travel demand and the volume of traffic on urban surface transportation systems and at the same time encourage more efficient use of existing roads, targeting specifically those conditions that routinely create stop-and-start traffic (idling is a particular concern in air quality) or in some cases shut down entirely the flow of vehicular traffic as in the case of accidents, large-scale events (such as sporting events or concerts), or inclement weather.

Because the CMAQ program has been one of the most successful (and, ironically, least publicized) government environmental initiatives of the past generation, and because of the sheer reach of its sponsored programs, it is difficult to list comprehensively the projects funded under its aegis. The program invites projects that expand existing programs or systems or introduce cutting-edge initiatives and/or propose pilot programs. Tradition and innovation thus have become hallmarks of the federal government's response to congestion mitigation.

Certainly the most consistently funded project proposals over the past 20 years center on projects designed to improve existing public transit systems, from infrastructure repairs and renovations to software updates to ensure smoother and more reliable service as a way to attract additional riders. But funded projects have also included encouraging employer-based transportation demand management (TDM) initiatives, such as flexible work schedules for employees, providing incentives for employees who carpool, and reducing the amount of corporate-sponsored travel by encouraging virtual conferencing. In addition, the CMAQ program has funded informational seminars, Internet sites, and weekend retreats to tout these shared-ride projects.

Effective congestion mitigation, however, relies primarily on improving the surface transportation system itself—and consequently much attention, and much funding, has been given to providing parallel highways systems to reduce traffic snarls and limit idling or adding additional lanes to off ramps to cut down on traffic backing up into travel lanes, or renovation and resurfacing projects to

rehabilitate heavy-use roadways. In addition, innovative proposals have been funded to build new shopping plazas, hotel facilities, spacious sports/concerts venues, and even local government complexes outside metropolitan areas as a way to attract vehicular traffic outward rather than inward. Although congestion relief relies on improving traffic flow and minimizing starting and stopping, real impacts in improving air quality rest ultimately in two areas: cutting down on the number of vehicles using the roadways and ensuring that those vehicles are in prime operating condition.

Projects have been funded to construct high occupancy vehicle (HOV) lanes or have provided special access around long-term construction projects to vehicles with multiple occupants. Outdated, boxy buses with traditional seats have been replaced by sleek, comfortable new models with ergonomically appropriate seats, wider aisles, and bigger windows to encourage higher patronage.

The CMAQ program has also addressed the fact that just 10 percent of the cars on the road are responsible for 60 percent of all emissions. Auto Club data indicates that Americans, perhaps leery over continuing economic uncertainties or the apparent random fluctuation of gasoline prices, have begun to hold on to their vehicles longer. Just 25 years ago the average age of a car on America's roadways was seven years; in 2013, that number was almost 12 years. Although many owners have kept up maintenance on their automobiles (and despite the Obama administration's valiant Cash Allowance Rebate Program, the so-called Cash-for-Clunkers initiative), the inevitable result is a massive number of vehicles with aging engines and increased emissions. Thus, the CMAQ program has beefed up emissions inspection programs, updating their software to improve accuracy and efficiency.

Finally, congestion mitigation policy has targeted urban programs designed to make cycling an attractive transportation alternative—enhancing highways with bike lanes, providing security racks for parking bikes, providing basic maintenance stations, encouraging businesses to provide support—and to encourage cities to accommodate pedestrians by providing secure paths, bathroom facilities, and smooth riding surfaces.

In conclusion, successful implementation of congestion mitigation strategies to reduce automobile emissions requires the cooperation of multiple

levels of local and state governments as well as business support and public awareness. These have become the hallmarks of the campaign to improve air quality through congestion mitigation.

Consolidated Rail Corporation

Railroads have long been an integral element in America's transportation history, transporting both passengers and freight throughout the country. However, the post–World War II period was marked by a significant decline in the importance of railroads to the U.S. economy. Acquisitions and mergers were seen as a way of surviving as railroads continued to diminish in importance. By the early 1970s, there were six major railroads serving the northeast and

the midwest: Central Railroad of New Jersey, Erie Lackawanna, Lehigh and Hudson River, Lehigh Valley, Penn Central, and Reading. Beset by falling revenues and unable to keep tracks and equipment in proper repair, these railroads began to fold in the first years of the decade.

With railroads unable to survive on their own, the government stepped in following the passage of the Regional Rail Reorganization Act of 1976 to create the Consolidated Rail Corporation, popularly known as Conrail, out of the remains of Penn Central, which had been formed in 1968 by the merger of Pennsylvania and New York Central Railroads, and five other bankrupt railroads. At the time, Penn Central was responsible for 20 percent of all freight delivered by rail in the United States and for 70 percent of passenger rail service in 16 northeastern and midwestern states. The United States Railway Association was established as a nonprofit government corporation and charged with monitoring Conrail and serving as its banker.

In 1980, passage of the Staggers Rail Act removed most economic restrictions on railroads, allowing them to become more competitive with the trucking industry. The creation of the National Railroad Passenger Corporation (Amtrak) and the transfer of financial responsibilities to states further eased financial burdens for Conrail and other railroad freight carriers. In 1981, a plan was devised to sell Conrail, which had continued to be besieged by poor management, labor problems, and other issues, to private investors. Instead, Conrail was ultimately sold as a public offering.

Early Days

In the 1970s, the survival of freight trains was continuously being threatened by long-haul trucking and airfreighting. By 1973, it was estimated that bankrupt railroads were losing approximately a million dollars a day. Three years later, Conrail was created by the U.S. government after it purchased assets of Penn Central and several other bankrupt railroads for \$3.4 billion.

Upon its creation, an independent board of directors, made up of members appointed by the U.S. Department of Transportation and the United States Railway Association, was charged with establishing policy for Conrail's operations. The initial plan for Conrail had been that it would become an independent entity by 1979. Instead, despite

receiving \$6 billion in federal funds, Conrail was on the verge of total collapse.

In conjunction with deregulation of the airlines and the trucking industry, President Jimmy Carter began pushing for deregulation of the railroads, resulting in the passage of the Staggers Act of 1980, which gave Conrail a good deal of flexibility in setting prices and removed most anti-trust restrictions. Railroad officials contended that government controls had stymied the ability of railroads to actively compete with trucking companies and prevented them from responding to rising inflation. Over the course of 1980, Conrail lost some \$244 million, and nine railroad carriers declared bankruptcy. The lack of maintenance funding meant that tracks and equipment were often in poor repair.

Up for Sale

By 1981, Conrail was regularly traveling 17,000 miles of track, delivering goods in 17 states. That same year, Secretary of Transportation Drew Lewis estimated that Conrail would require some \$4 billion in additional subsidies over the next four years in order to stay afloat. In response, President Ronald Reagan submitted a plan to Congress that called for selling Conrail piecemeal.

Subsequently, 15,000 rail workers marched on Washington. Congress rejected Reagan's proposal, choosing instead to approve a plan that would ensure Conrail's survival by making it self-sufficient and preparing it for eventual sale and rebirth while keeping it intact.

In July 1981, as part of the Omnibus Budget Reconciliation Act, Congress established a timetable for the eventual sale of Conrail. In order to keep it afloat in the interim, Congress authorized \$262 million for operating costs and provided another \$400 million for labor protection expenses. All passenger services in New York, Connecticut, Maryland, New Jersey, Massachusetts, and southeastern Pennsylvania were transferred to Amtrak, the government-subsidized passenger rail service.

One of Conrail's first priorities was to cut labor costs. Since 1973, Conrail had been required to pay approximately 11,000 employees stipends of between \$500 and \$1,800 a month until they reached the age of 65 as a result of agreements reached with railroad employees when Conrail had been created. Under the new guidelines, nonunion wages and

benefits were cut, and new procedures for collective bargaining were instituted. The revamping of Conrail's employee benefits was met with skepticism and threats of strikes.

By the end of 1981, Conrail was succeeding in returning a profit for the first time in its history, and plans for its sale proceeded. By that time, Conrail had received government funding of \$7.6 billion. The top three bids were from the Alleghany Corporation, J. Willard Marriott, Jr., and the Norfolk Southern Corporation. Critics of selling Conrail to a private corporation generally focused on the negative impact of job losses, cuts in freight service, potential exploitation, and lack of confidence in Conrail's ability to succeed without government help.

Many members of Congress were also afraid of problems that could ensue in the case of a resale outside congressional control. In June 1981, federal subsidies to Conrail ended. Under the guidance of Chief Executive Officer Stanley Crane, Conrail's profits had climbed to some \$500 million by 1984. Crane had achieved the turnaround in large part by cutting labor costs in half and reducing mileage by one-fourth.

Sold!

Ultimately, the decision was made to sell the 85 percent of Conrail owned by the U.S. government as a public offering. With more than 18 million shares up for sale, the Conrail stock was the largest public offering in U.S. history. On March 26, 1987, the government netted some \$1.9 billion from the sale combined with cash payments from Conrail. With that move, Conrail became a private entity. In 1997, Conrail was acquired by Norfolk Southern Corporation and CSX Corporation, with each corporation becoming responsible for one-half of Conrail's services, effective June 1999.

Thirty years after the passage of the Staggers Rail Act, both scholars and government and railroad officials were virtually unanimous in their praise for the deregulation of the railroad industry, which had allowed Conrail to succeed financially and paved the way for its eventual sale. That action is now considered one of the major successes of President Jimmy Carter's administration.

Due to financial solvency, railroads reinvested some \$511 million in capital improvements between 1981 and 2009. According to the Department of Transportation, the accident rate for that

same period declined by 65 percent as a result of those improvements.

Construction Management

Planning, design, construction, and operation of surface transportation infrastructure projects—primarily highways and transit facilities—have traditionally been funded and managed by public-sector transportation agencies. Since the establishment of the Highway Trust Fund (HTF) in 1956, funding for highways and, later, other surface transportation facilities has derived chiefly from automotive fuel taxes gathered at the state level, remitted to the federal government, and distributed to the states in proportion to their respective contributions.

While sufficient for many years, recent improvements in vehicle fuel economy and reductions in

Construction underway in 2013 on the Innerbelt Bridge project in Cleveland, Ohio, where the interstate highway crosses over the Cuyahoga River. The state project has been accelerated by using a design-build-finance (DBF) approach with a private-sector partner. The DBF approach means that the private-sector partner partially or totally funds the project development using its own capital, or it arranges for short-term financing in anticipation of being paid in full by the public sector at a later date.

total vehicle miles traveled have reduced these fuel tax revenues to the point where the HTF has begun to run a deficit that has required general fund contributions to meet state funding obligations. This comes at a critical time when the interstate system and other components of the U.S. surface transportation infrastructure (for example, state highways and bridges) are approaching the ends of their design lifetimes and are in need of significant repair or replacement.

In response to these pressures, the role of the private sector in public surface transportation facility development expanded in the 1990s with the passage of the Intermodal Surface Transportation Efficiency Act of 1991. The federal government has been experimenting with alternatives to the traditional public-sector-driven approach to the creation and maintenance of surface transportation facilities

in the United States. These approaches focus not only on creative financing vehicles for transportation facilities (for example, the Transportation Infrastructure Financing Innovation Act, TIFIA) but also on the closer engagement of the private sector in all phases of the project life cycle. These public-private partnerships (PPPs) are designed to leverage private-sector innovation, capital, and capacity to design and implement surface transportation projects that might not be achievable or affordable in a timely fashion if left to traditional public-sector transportation programming.

According to its proponents, a public-private partnership capitalizes on traditional strengths of the private sector—innovation, cutting-edge technology, and access to private capital and labor markets among them. In this view, the private sector is often better positioned to build, if not finance,

operate, and maintain the country's surface transportation infrastructure. Critics argue that ceding these responsibilities to the private sector reduces the degree of accountability to the voter for these transportation services and may result in the neglect of legitimate geographical transportation or social needs to the benefit of market priorities.

In its PPP programs, the U.S. Department of Transportation distinguishes between new and existing facilities and recognizes a gradient in the levels of public-private participation among the various partnerships. From more to less public responsibility for new facilities: Private Contract Fee Services, Design-Build, Design-Build-Operate-Maintain, Design-Build-Finance, Design-Build-Finance-Operate-Maintain, and Build-Own-Operate. For existing facilities, two PPP frameworks are examined: Operate & Maintain Concession and Long-Term Lease Concession.

Private Contract Fee Services

While retaining ownership and ultimate responsibility for their transportation facilities, public-sector agencies often outsource project management responsibilities to private-sector firms to capitalize on the latter's expertise and capacity to accelerate the implementation of transportation projects. In addition to facility construction projects, state agencies may also rely on the private sector for financial management and capital investment services. Examples of projects typically contracted to private-sector firms include highway construction and widening, and bridge construction or replacement.

An example of the benefits of this type of arrangement was the \$5.3 billion South Carolina "27 in 7" effort, which resulted in the completion in seven years of over 200 surface transportation projects originally scheduled to require over a quarter century to complete. The largest initiative of its kind, it employed financial incentives and disincentives to streamline strategic planning and financial management and coordinate design and construction activities.

Design-Build

Usually addressed in separate contractual agreements, a design-build arrangement combines architectural/engineering services and construction into a single fixed-fee contract between the transportation agency and one or more private-sector firms.

The public sector retains responsibility for securing project financing, initial planning, and facility operations, maintenance, and ownership.

A 2006 assessment of design-build project effectiveness concluded that some of the largest advantages of this public-private arrangement came in the timeliness of project execution and in cost savings realized by private-sector innovation and the less adversarial relationship established between public and private sectors in the process of project management. The four-segment, 91-mile-long SH 130 component of the Central Texas Turnpike System was approved in 2001 and completed in 2007. Because of the design-build public-private partnership, the facility was delivered under budget and 25 years sooner than would have been possible under traditional contractual arrangements.

Design-Build-Operate-Maintain

A further consolidation of transportation facility life cycle responsibility is achieved by combining into a single contractual agreement responsibility not only for the design-build portions of the project but also for long-term facility operations and/or maintenance. The public sector retains responsibility for arranging the financing of the project.

Significant benefits attributable to the design-build-operate-maintain (DBOM) arrangement are recognized through an increased focus on the facility's entire life cycle, which enables the contracting entity to reduce project costs that accrue over the productive life of a transportation facility. As opposed to contractual and operational inefficiencies inherent in sequential design-build and operate and/or maintain contracts, a single contracting entity can design and construct the transportation facility with long-term operational and/or maintenance efficiencies in mind. The initial 9.5-mile phase of the three-phase, 24-station Hudson-Bergen Light Rail transit system, completed in 2000, was the first DBOM selected in the United States. Because of the efficiencies realized in this public-private partnership, this phase was estimated to have been delivered eight years sooner than would have been possible through the traditional multiple design/bid/award/construct approach.

Design-Build-Finance

When a public-sector project sponsor finds itself in a cash flow-constrained position or merely wishes

to defer payment for facility development services, it may elect to rely on the financial capacity of its private-sector design-build partner. In the design-build-finance (DBF) approach, the private-sector partner partially or totally funds project development by either using its own capital or arranging for short-term financing in anticipation of full public-sector repayment in the longer term. This arrangement involves the transfer of an enhanced degree of financial risk to the private sector associated with the uncertainty of the public agency's future project funding capacity as a function of state or federal appropriations.

An example of the DBF approach is the Innerbelt Bridge currently being constructed over the Cuyahoga River into Cleveland. The westbound lanes were constructed using a design-build arrangement between the Ohio Department of Transportation (ODOT) and the private sector. Because of a gap in available funding, ODOT is using a DBF approach to accelerate by three years the construction of the eastbound lanes.

Design-Build-Finance-Operate-Maintain

An extension of the DBF approach, design-build-finance-operate-maintain (DBFOM) is used to achieve fiscal and operational efficiencies across the entirety of the facility life cycle. In contrast to the short-term financing characteristics of the DBF approach, DBFOM arrangements are financed by long-term debt secured by future facility-generated revenue, most commonly user tolls, for the contractually specified duration of the concession. Project sponsors also find DBFOM arrangements attractive because they often provide access to new sources of equity and financing.

Two general categories of DBFOM frameworks are used in the United States. "Real toll DBFOM concessions" leverage facility toll (or other concession) revenue streams as sources for debt retirement and return on investment (ROI), though some public-sector funding contributions may be necessary. As a result, the private-sector concessionaires assume the risk that these operational revenue streams may not entirely meet their debt obligations and ROI forecasts. The Dulles Greenway in Loudon County in northern Virginia is a tolled facility that was privately financed and built and is operated by a private-sector partnership. Facility toll revenues secure the construction debt.

Facility financing risk is retained by the public sector in "availability payment DBFOM concessions." In this approach to facility development the project sponsor commits to a schedule of payments predicated on project delivery milestones and/or operations performance standards (for example, lane closure frequency and incident management) over the lifetime of the concession. This arrangement may be selected when the facility is toll-free or is not expected to generate a toll revenue stream sufficient to service the project debt. The Denver Metro Area Eagle Project includes 122 miles of commuter rail and light rail, 18 miles of bus rapid transit service, and other facility renovations and improvements. While the Regional Transportation District will retain ownership and all revenues from the project facilities, the private consortium Denver Transit Partners was awarded a 34-year DBFOM concession under which it will receive regular payments based on established performance metrics.

Build-Own-Operate/Build-Own-Operate-Transfer

At the far end of the continuum of public/private spectrum lies build-own-operate (BOO) and build-own-operate-transfer (BOOT), also known as build-operate-transfer (BOT). In these arrangements the project sponsor cedes to its private-sector partner(s) responsibility for design, financing, construction, maintenance, and operation for the duration of the concession. The ownership of the facility may be granted to the private consortium only for the duration of the concession (BOT) or in perpetuity (BOO). In the latter case (BOO), transportation projects are more likely than in other arrangements to be originally conceived by the private sector.

Operate and Maintain Concession

In an attempt to realize management, service, and/or technological efficiencies, an existing public facility owner may grant an operate and maintain (O&M) concession to one or more private partners in return for fixed-fee or performance-based payments. Services often provided under these arrangements include ongoing activities such as grass mowing and snow removal as well as facility maintenance and repair.

An O&M concession is often part of a public-sector strategic asset management approach that

attempts to achieve a longer productive facility lifetime through a level of upkeep and repair that cannot normally be provided by the facility owner. An O&M fee service contract was granted by the Alaska Department of Transportation and Public Facilities for the operation and maintenance of the Anton Anderson Memorial Tunnel, the first dual mode rail/vehicular tunnel in the United States.

Long-Term Lease Concession

While an O&M concession is appropriate for surface transportation facilities that do not produce a revenue stream (for example, nontolled highways or bridges), the public-sector financier/owner of a toll facility may grant a lease concession to a private-sector partner for the long-term operation and maintenance (and, sometimes, improvement) of the facility. Instead of being paid in regular or performance-based installments from scheduled or appropriated public funds, the concessionaire derives its cash flow from the tolls charged to users of the facility. A one-time concession fee charged to the private-sector partner may be used to defease the debt accrued by the public sector in the facility's construction. This transfers to the private-partner responsibility for retiring the construction debt using the toll revenue stream.

Built in 1958 and managed by the City of Chicago Department of Streets and Sanitation, a 99-year concession was granted to Cintra/Macquarie, a Spanish/Australian consortium, for the long-term operation and maintenance of the 7.8-mile toll facility. This was the first long-term lease of an existing toll road in the United States.

Construction Management, Public Relations and

The impact of infrastructure planning and construction on communities is often the subject of media headlines and sometimes legal disputes. As infrastructure plans are designed to improve the quality of life, construction activities initiated by such plans add useful functions that are eventually manifested to the public; yet such construction projects can be disruptive to the community.

The impacts on the community can be classified by type as impacts on individuals and households and as impacts on businesses (local and major chains). The process of identifying and mitigating these impacts calls for community impact assessment as part of an encompassing environmental assessment process.

The front stage of community impact assessment includes the geographic and demographic boundary of the assessment and, more importantly, the community profile. In the context of transportation, the impacts are generally classified under three main categories: availability of services, safety, and possible relocation of residents or businesses.

Public engagement was traditionally portrayed as a mechanism for maintaining a balance of power between citizens and their government in the process of decision making. The main role of this mechanism is to minimize the impacts and risks of failure of decisions made in the construction of transportation systems. Effective public engagement must be a continuous process starting early before the planning and design phases and extending to cover the whole project life cycle (including operation, maintenance, and even, in some cases, decommissioning).

Current Decision-Making Process

Decision making for the construction of transportation infrastructure is a complicated process

involving complex interactions among multiple stakeholders with diverse (and sometimes conflicting) interests. Community members, as the end users of the urban infrastructure services, form one important group of the stakeholders and traditionally participate in the process of decision making as a part of the feedback loop.

The decision-making process usually starts with “problematization,” which includes detection of the issues, identification of the main participants in the process (along with their interests), and realization of the alternatives. Once goals, objectives, and priorities are stated, data is collected and interpreted for preparation of a general plan, along with draft implementation programs. Social, environmental, and economic impacts of the general plan and implication program are assessed and the results are published for the community to offer feedback.

Once the feedback is collected and considered, an edited plan will be issued. The process has a recursive nature and is highly dependent on the decision makers and feedback providers. People who are truly interested and are able to serve on the planning team are suggested as candidates and the community selects a committee to represent it by participating in the meetings where the planning process and expected accomplishments are explained. Meetings with all participants are held regularly to bring them up to date on work and to collect their general feedback as a constructive step toward developing consensus about the plan.

Impacts on Businesses and the Community

The construction of highways and other urban transit services inevitably impacts businesses and communities. Damages to the urban cores and historical sites due to demolition necessary for construction, change in land use, traffic infiltration and intensification, noise, and risk to public safety during and after the construction phase are among other such impacts. The community usually reacts against any project that is perceived not to serve their interests or to jeopardize their safety.

In many cases, social trends may shift and can impact the community’s attitude. The case of the Spadina expressway in Toronto, Canada, is a case in point. It was stopped at the construction phase in early the 1970s under the pressure from a community group, although the project received a supporting vote from the majority of the neighborhood

in the planning phase in the 1950s. Therefore, it is critical to carefully analyze the nature of local communities and plan the community engagement process to ensure the community is truly aware of the impacts, construction schedule, and planned disruptions. Local residents, business owners, and other community representatives, as well as the city staff and planners, should partner as members of one team and actively collaborate on creating solutions to disruptions caused by construction and any concerns that the community brings up. Feedback from the public is absolutely essential in reaching effective solutions to minimize disruptions to the community and businesses during construction.

Community Engagement Process

The evolution of the community engagement process from a “public relations” exercise to a more “engaged partnership” has been highlighted as an objective in recent projects. In the past, community engagement was mostly limited to informing and educating the public with the aim of maintaining public support. The process is now evolving into other forms of consultations that employ two-way communication.

One public participation standard is the International Association for Public Participation (IAP2) spectrum, which proposes that public impact can be enhanced at five levels: informing, consulting, involving, collaborating, and empowering. At the lowest level, static tools such as Web pages and open houses are commonly used with the objective of providing the community with information regarding a specific project or decision impacts.

Most of today’s community engagement activities, however, fall under the consult, involve, or collaborate categories. These are levels at which surveys, polls, public meetings, and citizen advisory boards are common to achieve the higher objectives of partnering with the public in creating alternatives and informing the decision-making process through partnership.

Lately, various visualization techniques have also been acquired to enhance such communication through a better representation of complex concepts (such as changes in the character of the street, neighborhood, or city). In addition, the social web has facilitated a third dimension that includes versatile collaboration between community members for collective deliberation on complex topics. In the

context of infrastructure planning and construction, a major step that follows is how to integrate the impacts and solutions identified in the community engagement process into decision making.

Opportunities for Improvement

Despite the effort put into achieving progress, occasional community dissatisfaction, as portrayed by the media, indicates that the public involvement process may not have achieved all its objectives in some cases. This situation can consequently lead to the failure of the decision-making process as a whole. Several factors can cause such inefficiency. Impact assessments in general and environmental impact assessments (EIAs) in particular have been criticized for failing to achieve a number of their goals. Public anticipation and sometimes frustration due to the length of the assessment, planning, and implementation period is one of these critiques.

On the other hand, the shift of the power in the hierarchy of the decision makers sometimes redefines decision goals along the way in the project life cycle, which can result in the conflict between social norms/values and decision makers' objectives.

Furthermore, the current controlled mechanism of providing the community with predefined alternatives and diminishing their role as alternative generators and solution providers has been linked to a lack of innovative solutions for the development of infrastructure in general, and transportation systems in particular.

To overcome some of these shortcomings in the process of public engagement, a trend has emerged to replace the current "push" mindset in collection of feedback with a "pull" system of detecting demand and collecting feedback by leveraging the public with the tools available in the social web and online social media. Looking at the infrastructure project as a marketable product, some transportation planning agencies approach the process in a manner similar to how marketers engage customers in the field of commerce, and how the reverse marketing mechanisms collect the user innovation.

Last but not least, different phases of a project's life cycle have unique impacts on the community and businesses and must be addressed. Hence, the engagement of the community should not stop at the decision-making stage or once the design is finalized. To the contrary, it must reach beyond construction

to be integrated into the whole project life cycle as a continuous process.

Container Terminals

A container terminal is the set of facilities at a port devoted to the loading and unloading of containers through autonomous operations. One or more of these terminals exist in a cargo port that engages in

the transfer of containerized goods and is referred to as a container port.

Container terminals represent a recent perspective of serving maritime transportation. They appeared in the last 40 years because of the increasing use of the standardized box that can hold about 20 tons in weight and can withstand having five full containers stacked on top of it. Before 1970 only the New York Port Authority and the ports of Rotterdam and Singapore had invested in building and operating specialized container terminals.

Today, specialized container terminals are found in all seaports that serve international trade. They lift more than 50 million containers per year around the globe, as over 90 per cent of international non-bulk trade travels in containers, including cargoes that were previously considered not suitable for containerization. Containers handled are either full or empty. The empty ones account for more than 20 percent of the global container port throughput. More than 100 ports handle over 1 million TEUs (20-foot equivalent unit) per year, with two or more container terminals operating in the vast majority of them. Annual throughput in nine ports in Asia and in Rotterdam exceeds 10 million TEUs.

The transshipment (ship-to-ship) concept and the increasing transportation of intermediate goods along supply chains are driving forces for the rise of container handling, the operational restructuring of this handling, and the specialization of container terminals.

The modern container terminal is generally found in one or both of two types of ports. The transshipment hubs are designed to optimize the transfer of containers from one maritime vessel to another between networks of long-distance and/or short-distance (feeder) shipping services. While they are not directly associated with a direct hinterland, an indirect one does exist. The gateway ports are designed to service the needs of local, regional, and sometimes large, inland populations. They may transfer its cargo to an inland terminal to service its significant distant markets or may transfer cargo to local distribution or transload centers for further carriage.

A distribution center usually involves warehousing materials until needed while a transload center specializes in cross-docking the contents of seagoing containers into domestic trailers and the reverse, to

serve both a sorting function and the freeing up of marine containers for reuse near the port.

Some terminals may provide both gateway and transshipment services. Others are feeder terminals, where containers may arrive from either of the other two port types, but these are generally run using older equipment and the emphasis is on servicing the local population and the captive hinterland. Such feeder operations may handle a mix of containers and trailers on a single vessel, and the speed of terminal operations is not of paramount concern.

The success of container terminals is the outcome of the quality of their infrastructure and services, the operational productivity within terminal cargo handling, an efficient interface with inland transport systems, and their integration in modern supply chains.

Operating Container Terminals

The growing quantities, along with the increased size of container ships, which almost doubled within the first decade of the 21st century, imply investments in infrastructures and dredging to enable container ports to serve larger vessels. Berth and channel depth have become more important, and berth length is more crucial to servicing seagoing container flows.

They are also associated with a fundamental change in container terminal operations, as new-generation yard equipment modern cranes offer terminal berth productivity improvements. Competitive container terminal facilities provide capital-intensive cranes able to manage as many lifts per hour, or the capability to lift multiple boxes side by side at one time, as container ships do not have onboard cranes (as bulk carriers do).

Important pieces of yard equipment include rubber-tired gantries and straddle carriers to pick up or drop off containers over stacks dockside to and from nearby container stacking areas, thus being the last, or first, link in a container terminal, and container rail-mounted gantry cranes that position containers along a linear stacking yard. Technological advancement led to the introduction of automatic guided vehicles used for grounded container operations.

The latest models of the latter aim to ensure the required performance and improved reliability as well as reduced fuel and maintenance costs. An example of these are the electrically driven diesel

hybrid automatic guided vessels that are already in use, for instance at the ECT Delta terminal in Rotterdam.

As machines carry containers, and technological advancements allow for almost full terminal automatization, labor and once-powerful port labor organizations have seen their numbers, role, and influence diminish.

The productivity of the modern container terminal is highly dependent on the layout of terminals as well. Ample storage space to stack containers dock-side and berths designed to accommodate quick ship turnaround are important for effective dock-side operations between the ship, the crane, and the container storage areas. The structure and configuration of container handling operations change container terminals that tend to occupy more space for moving, storing, temporary or permanent, and providing value-added facilities for containers and the goods transported within them.

Most important is the way that the container terminal operators manage these yards. As a buffer between the container ship and the hinterland, the yard of the terminal needs to resolve operations at berth, movements within the terminal, complex stacking processes, unforeseen situations like repositioning of several containers, random pickups by customers, and delayed container ship arrivals.

Landside operations go well beyond the unloading and storing of full and empty containers, not least because container terminals serve as the only transport system that allows shipments to be used by ship, rail, and road modes of carriage. Trains and trucks operate within or near the yard, and the smooth integration of the various modes is key to terminal competitiveness. The common practice is the handling of quantities of containers through sophisticated electronically applied and monitored operations linked with supply chains.

To avoid disorganized development of container terminal facilities and allow a prompt response to changing demand, planning is as flexible as possible. This planning aims to enable anticipation of different scenarios, thereby minimizing the risk of losing markets and enhancing port profitability. It is used to resolve problems arising from both foreseen and unexpected situations, such as greater demand, new port policies, greater competition, the loss or incorporation of areas with or without equipment, and interruptions to terminal access.

Along with other factors traditionally included in the calculation of port terminal capacity, container terminal planning is commonly dynamic so as to facilitate adaptation to variations in demand and unexpected situations that, along with forecasting difficulties, mark the container market.

One of the first tasks when planning a terminal is to determine port demand and capacity. For the estimation of capacity, one needs to determine what may be expected at the port berth and the need for

Cranes at a container terminal in the port of Hamburg, Germany, in 2011. Worldwide, container terminals are handling over 50 million containers a year, and more than 100 ports handle over 1 million TEUs (20-foot equivalent units) every year.

storage capacity. In the case of an import container, capacity is calculated from the time the container is unloaded to the time it leaves the port (that is, it is equivalent to the capacity to unload a container, have it remain for some period in the yard, and eventually exit through the gate). For an export container, the steps are similar but in reverse, and for a transshipment container, capacity involves loading and unloading the container plus its stay in the terminal.

Integration in Supply Chains

Container terminals are increasingly elements in value-driven chain systems, not simply places with particular functions. With shippers transporting vast quantities of final and intermediate goods, opening the box within nearby terminal locations, or even within the terminal, is as crucial as the efficient and effective operational integration of container terminals in multimodal transport chains that allow the provision of value-added services and logistics at locations where, for example, inland depots and logistics-related service providers exist.

The terminal captures value for itself and for the chain (that is, shippers, third-party service providers), maritime companies demand further services specialization within the port area, and firms providing port or value-adding services and logistics are interested in the development of logistics pathways in which the terminal is embedded.

Container terminals are thus associated with a growing number of stakeholders. The relevant cluster involves multiple actors who are involved within the supply chain, and the operation of all of them conditions port competitiveness. This implies a change in port governance, with port authorities, that had acted as a landlords of private operated terminals only, assuming a more active role in networking these actors, in resolving collective problems like port marketing, and in promoting the interest of all those involved in the relevant container terminals cluster that operates within a given port.

All the above have led to the spatial and functional expansion of the activities of the container terminals, as well as those economic and operational activities related to it, a process described by Theo Notteboom and Jean-Paul Rodrigue as hinterland and foreland “port regionalization.” The latter associates container terminals with economic growth, yet it generates several challenges in the relations with port cities that see port terminals

seeking further expansion of their activities the more competitive they are, in turn generating a number of negative externalities such as noise pollution and usage of scarce land space.

Terminal Entry

The changes in the organization of container handling resulted in the transformation of port governance. A key move has been the progressive entry of private terminal operators, an opportunity for entry and rise of international terminal operators. This implied a fundamental shift in the concept of “port,” from one whose operations are coordinated and controlled by a public agency whose actions are shaped by local and regional interests to one that is made up of independent terminals whose activities are determined by the commercial interests of its international long-term lessors—a shift termed by Brian Slack and colleagues as “the terminalisation of seaports.”

The acquisition of a concession to provide terminal services, along with variable commitments to infrastructure building, is the dominant mode of private entry in all continents. Governments or port authorities commonly retain the initiative of planning. Procedures for awarding concession differ between regions, within countries, even within a given port.

In Europe and the United States, where port authorities transfer the rights to provide port services to the private sector, dual practices exist, as calls for tenders for a new terminal are combined with direct talks with incumbents, whereas corporatization and listing of the seaport in the stock exchange is seen as a precondition in some cases. In the booming ports in China public–private joint ventures involve public-sector operators that retain a share of at least 75 percent and foreign investors.

Different types of container terminals emerge as regards the responsible operator. Some remain public or state run, with facilities used by all commonly on a first-come, first-served basis. Others are operated by terminal operators that invest directly in operation, handling facilities, and, when applicable, the construction of the terminal. Stevedores, the companies that act as terminal operators, expand into new markets to replicate their expertise in terminal operations and to diversify their revenue geographically. The Port of Singapore Authority (PSA)

is the largest global terminal operator coming from a stevedore background.

Similarly, shipping companies, either alone or in collaboration, also operate container terminals. These terminal facilities operate on a single-user-dedicated base, where major shipping lines sign long-term contracts for exclusive terminal use, or alternatively are open to third-party shipping lines. In many cases hybrid structures are formed with separate business units or sister companies active in terminal operations. APM Terminals, a sister company of Maersk, is the largest global terminal operator from this background. Joint ventures of carriers and terminal operators also exist, whereas there are fewer partnerships among the shipping lines that have multi-user long-term contracts to share out the terminal usages.

Ports witnessed the emergence of international terminal operators operating a global portfolio of container terminals across various ports, regions, or countries. In the 1990s carriers and terminal operators doubled their involvement into terminal management. Since then, international terminal-operating companies have continued to take a bigger share of the global container handling market at the expense of both family-controlled stevedores and state-owned enterprises.

In the last decade they were joined by the various financial interests ranging from investment banks and retirement funds to sovereign wealth funds attracted to the port container terminal sector as an asset class and for revenue generation potential. The majority have an indirect management approach, acquiring an asset stake and leaving the existing operator to take care of the operations. Others manage directly the terminal assets through a parent company, an example that marks the extent of this finance being Dubai Ports World (DP World), a branch of the Dubai World sovereign wealth fund, marking the extent of that financialization trend.

Today the four major container terminal operators—Port of Singapore Authority Corporation (PSA), Hutchison Port Holdings (HPH), Dubai Port World (DP World), and APM Terminals—handle 46 percent of global container trade and the 10 major ones approximately 65 percent of world container traffic, whereas a decade ago they handled 45 percent only.

These trends changed the nature of the competition between container terminals and the ports

that host them. The competition between ports in different locations for the handling of containers, commonly termed “interport competition,” is now accompanied by intraport competition, a situation where two or more different terminal operators have jurisdiction over respective terminal areas, from berth to gate, within the same port and are vying for the same market. In bigger ports, for example Hong Kong, it takes the form of intraterminal competition with companies competing to provide the same services within the same terminal.

Responding to market development, port policies with reference to container terminals have been developed. The emphasis is on the integration of ports to multimodal transport networks. It is also on the facilitation of intraport competition that allows for operational flexibility and innovation, and limits excess rent seeking by those operators maintaining monopoly positions. With few exemptions, port authorities develop policies to promote it whenever the scale of the operation is such that it allows more than one terminal operator to be active in a specific port.

Containerization/ Container Shipping

Containerization is a process in which freight movement by marine, rail, and truck modes and intermodal terminal operations are gradually transformed so that most manufactured cargo moves in shipping containers in a range of standard sizes that are loaded and unloaded by specialized container-handling cranes and vehicles at container terminals. The efficiency of cargo handling, intermodal transfer, and turnaround time at ports have greatly increased, contributing to a reduction in transportation costs for many types of manufactured goods.

Historical Development of Containerization

From the practical inception of for-hire trucking in the 1920s, railways began to carry straight trucks and semitrailers on flatcars between major railway terminals. Known colloquially as “piggy-back” or more formally as “trailer-on-flatcar” (TOFC) service in the United States and Canada, railway flatcars were modified with folding bridges so that vehicles could be driven from specialized loading docks over the length of the train. This cumbersome and laborious “circus-style” of train loading offset the fuel and labor cost savings of shipping individual trucks by rail over long distances. In the United States, piggy-back service faced serious obstacles from the Interstate Commerce Commission (ICC), which became responsible for interstate trucking in 1935, and the Teamsters, whose truck-driving jobs were at stake, also opposed the innovation. Thus piggy-back service did not really take off until the middle 1950s when the ICC relaxed its regulatory restrictions and railroad consortia such as Trailer Train in the United States were formed to rationalize piggy-back service on a number of competing railroads.

While there were a number of initiatives to reduce freight-handling costs and to containerize freight for different modes in different regions of the world, containerization in the United States was heavily influenced by the innovative spirit of one aggressive and innovative entrepreneur and former trucking company owner, Malcolm McLean. McLean was motivated to reduce the costs incurred in traditional break-bulk operations as freight was

transferred from trucks to coastal shipping routes on the eastern seaboard. Traditional truck trailers were not ideal for this purpose because “fishy-back” wasted the volume between truck trailers and the deck that was required for the wheels. McLean’s original goal was to design a shipping container for transshipment between trucks and World War II vintage T2 tankers that was inaugurated in 1956 in a test shipment over the coastal waters from Newark, New Jersey, to Houston, Texas. A variety of experiments with container shipping in the 1950s shared one common element: there was no consensus on whose standard container was to be used on a worldwide basis.

The negotiation of container standards pitted the American Standards Association (ASA) against the International Standards Organization (ISO), and within each of the two nongovernmental organizations there were competing enterprises that had already sunk considerable capital into containers that were incompatible.

By the early 1960s an American dimensional standard had emerged: 8 feet high, 8 feet wide, and 10, 20, 30, or 40 feet long, but 24-foot and 35-foot containers remained in service; in addition, a second series of smaller containers was also recognized, some measured in feet and others in meters. To realize their full potential, containers had to be stackable and secured with standard steel fittings welded to the corner post with fasteners so that any container could be locked to any other container. Most of the corner fittings were patented, and after a modified American Sea-Land design was finally adopted by the ISO as the world standard in 1965, it turned out that it would not withstand the stresses imposed by European freight-train couplings or high seas in a marine mode.

Perhaps the most notable feature of containerization was the inability of the United States and the rest of the world to negotiate a workable standard container size and locking mechanism. The question of container standards was in play for fully 10 years and the various container companies spent millions adapting their containers to a standard size and locking mechanism that was in flux. If a single container standard was elusive, the shipping industry was quicker to settle on a standard measure of container shipping, the TEU: a “20-foot equivalent unit” based on a container that is 8.5 feet by 8.5 feet by 20 feet in length.

Containerization Trends and Implications

International container traffic, measured in TEUs, has grown quite steadily at an average annual rate of about 5.3 percent. However, this growth has not come without a considerable structural transformation that is dominated by growing concentration of container ports, shipping firms, ships, shipbuilders, and container manufacturers.

First, container traffic has become more concentrated in a relatively small number of very large container ports. As a consequence of growing container ship size, only the largest ports are accessible to long-haul shipping. Thus there is a growing functional differentiation of container ports into three categories: hubs, pivot ports, or load centers handle the largest ships coming the greatest distances and offload containers for transshipment to smaller ports; direct ports are served by large ships but have no transshipment function; and feeder ports are served by only the closest load centers.

Second, container traffic is carried by container ships that are owned by a diminishing number of very large shipping companies. Shipping companies are consolidating by mergers; one of the most notable is the takeover of Sea-Land by Maersk, creating the largest single container shipping company in the world. The concentration of corporate power is often indirect when shipping companies undertake strategic alliances with other shipping companies or with container port operators. Strategic alliances give shipping companies greater bargaining power with port authorities, terminal management companies, and landside carriers.

Third, container ships are growing larger and more fuel efficient. The first generation of container ships in the 1960s carried up to about 1,000 TEUs. Post Panamax container ships now have a capacity in excess of 10,000 TEUs with operating costs about one-third of a Panamax vessel of about 4,500 TEUs. Indeed, a new generation of Malacca-max vessels of about 400 meters in length and carrying 18,000 TEUs will have a draft of up to 21 meters, the maximum practicable draft for eastbound ships serving Singapore and east Asian ports.

Fourth, the number of service providers to the container shipment industry is growing more concentrated. Over 80 percent of all container ships are now built by just four shipbuilders: one is Japanese and three are Korean. Virtually 100 percent of all shipping containers are now manufactured in China.

Containerization of marine, rail, and road traffic has been a significant technological change affecting transportation services around the world. It is an ongoing process of growth and structural change that has facilitated globalization and international trade but with ultimate impacts that are uncertain.

Cordon Travel

Despite the great diversity among the cities of the world, almost every metropolitan area in the modern world faces problems surrounding rush hour traffic. The exact nature of traffic-related problems may have regional variations, but all cities would like to minimize those problems. Unfortunately, most cities are not able to add new roads due to space restrictions and the significant resources required for such projects. For these reasons, administrators and researchers have investigated and, in some cases, implemented fees for traveling through high-traffic metropolitan centers, often referred to as "cordons."

While tolled cordon areas are not widespread in the United States, the concept is similar to that of toll roads. The roads passing through these areas are reserved for people who need to be someplace

particularly quickly. An additional similarity between cordon areas and toll roads is that they have both become easier to maintain due to automated tolling technologies.

Why and Where Cordon Fees Exist

Such congestion pricing is most commonly put into place in cordon areas, which are restricted areas surrounding city centers. Outside of military applications, cordon areas are typically set up for the purpose of controlling the number of vehicles entering a city center. Cordon travel is based on certain capitalist economic theoretical assumptions. The proponents of cordon travel point out that, based on the laws of supply and demand, traffic occurs because demand exceeds supply. This lack of supply (that is, road space) causes a shortage; thus, traffic jams ensue. From this theoretical standpoint, fees are set to determine an “equilibrium price.” At such a price, traffic would be acceptable in density (thus traffic jam free) and the price of travel would be low enough to be acceptable to the greatest number of commuters possible. This same set of free market-oriented economic precepts could also be applicable to other services, including trains, buses, telephones, electricity, and other public services and utilities.

There are a number of problems city administrators address that could be solved by limiting traffic to certain areas of a city. First, there is a certain cost of maintaining roads in the form of mowing green spaces, patching roadways, and other tasks that require outlay for materials costs and worker wages. Cordon fees would both lessen the wear and tear on the roads in a target area and pay for at least a portion of the upkeep. Paid cordon travel could also be utilized to limit air pollution and noise pollution; the benefits of such an improvement are obvious.

It is also argued that if traffic through cordon areas were lowered, there would be a corresponding lowering of traffic accidents. Finally, there are more abstract economic costs of traffic congestion, such as worker hours lost by being late for work. Thus, enterprises located in the cordon area may see an increase in productivity due to the fact that employees are able to arrive at work on time more reliably.

Electronic toll collection technologies could greatly expedite implementing potential cordon travel fees. These technologies have simplified the

infrastructure needed to enact cordon travel by requiring only an array of sensors and cameras as opposed to a series of toll booths, worker wages, and all of the amenities needed to allow workers to operate toll booths (bathrooms, air conditioners, break rooms, etc.). Therefore, a greater number of cities are either considering or planning to establish cordon areas.

While the most common method of establishing corridor fees is through cordon travel, there are alternate methods to achieve this goal. Freeways passing through a downtown area may be turned into toll roads; passengers may then be charged by the distance traveled through the targeted area. In this situation, the toll may be switched on or altered during peak travel times. This can be established through either toll booths or electronic tolling systems, such as EZ Pass. Preexisting high occupancy vehicle lanes (HOV) could also be used to establish a cordon travel system.

Typically, HOV lanes are designated only for vehicles with a certain number of passengers (typically two, including the driver). If administrators wanted to use HOV lanes for cordon control, they could issue special licenses to individuals who regularly travel to targeted areas that would allow them to use these lanes without following standard HOV rules. This would have the effect of directing those who regularly travel to the target area to the HOV lane.

Cordon fees were first implemented in Singapore as part of the Singapore Area Licensing Scheme in 1975. It took some time for other areas to accept such fees, in large part due to hurdles poised by preexisting infrastructure. Later implemented systems went into place in Rome (2001), London (2003), Stockholm (2006), and Milan (2008). Cordon pricing has been less politically popular in the United States, but cities currently considering such a price scheme include San Francisco, Miami, Minneapolis, Chicago, and Seattle.

It would be incorrect to believe that paid cordon travel has been implemented everywhere it has been considered. This type of pricing has been rejected either unilaterally or democratically in Hong Kong and certain areas of the United Kingdom (including Edinburgh, West Midlands, and Greater Manchester). Large-scale cordon pricing has also been rejected in New York City; however, some concessions have been made in this regard by

charging greater amounts on certain expressways and the George Washington Bridge during certain peak hours.

Concerns and Criticisms

Cordon travel fees are not without their detractors. The primary objections bring up not only the research and economic theory backing up cordon fees but also the potential negative social impact that could occur if cordon fees were put into place. Opponents to cordon travel schemes argue that cause and effect has never been properly established in the relationship between setting up cordon fees and lessening traffic.

These critics argue that traffic jams are not purely based on the number of cars on the road, and that the number of cars is but one of very many variables that contribute to traffic jams. Put very simply, traffic jams are caused by many people trying to do the same thing at the same time, and the number of cars needed to cause a traffic jam is fairly small.

Not all objections to cordon fees rely on the assumption that the theory behind such schemes is faulty. If we are to assume that cordon fees do actually keep people out of areas at peak times, it can then be easily argued that these fees are harmful to businesses within the target area, as at least a portion of potential customers would be kept away from those shops. This complaint is exacerbated by accusations of corruption. Beyond simply being inconvenient, roads are built with taxpayer money and cordon fees adversely impact those with fewer resources to pay additional costs for use of those roads.

Those critics who are not so concerned with theoretical flaws or the economics of business point out that cordon fees could have negative impacts on society. At the very least, enacting tolls to areas that were previously free to access would be very unpopular. Critics have also questioned whether the fees are actually enacted for the greater public good or whether these fees are actually put in place as an additional revenue stream for society's elites. The theory behind cordon fees assumes that

many are traveling to cordon areas when they do not have to.

This thinking may be backward if the areas in question are primarily business oriented. If so, the vast majority of travelers to the cordon zone will continue to congest the roads, and yet another fee will be imposed on working people who may not be able to afford the additional cost. Finally, critics argue that the implementation of fees "unduly" benefits those who live in cordon areas, as they do not have to pay the fees to access employment; this point is especially sharp if those who live in the cordon area are of high socioeconomic status.

D

Demand-Responsive Transit, Evaluation Studies of

A demand-responsive transit (DRT) system is a means of transportation for the public that is known by its flexible routing and scheduling. Having the availability of this type of transportation system has been especially beneficial for that segment of society with limited access to conventional public transportation. According to the Transit Cooperative Research Program (TCRP), there are about 1,500 rural and 400 urban DRT systems in the United States.

The definition of DRT has been continuously developed throughout the years. It is generally characterized by its flexible routing and shared rides, and the Federal Transit Administration defines it as a “transit mode comprised of passenger cars, vans or small buses operating in response to calls from passengers.” DRT has been identified with other terms such as dial-a-ride, flexible transport service, and demand-responsive service. With DRT having a large range of definitions, it confirms that not all providers of DRT systems are identical. DRT serves a variety of riders and is not focused on any specific type of rider.

Fixed-route transit (FRT) and DRT systems are the two broad categories in transit systems. The

most cost-effective are the FRT systems having a large loading capacity and a predetermined schedule. In comparison with fixed-route services, the DRT still has low productivity and high per-trip costs. The flexibility of the DRT system is what makes it more appealing than FRT. The movement of individuals from inner cities to the suburbs has created less demand for the fixed-route transit options and also increased the price per rider. Therefore, in the less dense areas the DRT system can be more cost-efficient by having dispersed trip destinations.

Since the 1960s, DRT systems have been proposed, although it was not until the 1970s that the simple DRT systems were implemented in the United States. During this time, the manual dispatching system in use was expensive and excessive. Since then, there has been an incredible increase in the use of DRT systems. A large increase in 1990 was due to the Americans with Disabilities Act (ADA), which required the availability of “paratransit” services for individuals unable to use the fixed-route services. Many of the riders who currently use DRT are in rural areas with limited access to a privately owned vehicle.

Based on a Government Accountability Office survey, since 2007 the demand for ADA paratransit trips in the United States increased for some transit agencies, and costs for providing the trips remained high. The average number of annual ADA paratransit

A National Express “dot2dot” vehicle outside a terminal at London Heathrow Airport in 2008. Many such airport express vans and buses are forms of demand-responsive transit.

trips provided by a transit agency increased 7 percent from 2007 to 2010; from 172,481 trips in 2007 to 184,856 trips in 2010. Increases in demand for ADA paratransit services were driven by the 10 largest transit agencies, measured according to the population size of their service areas. Also, ADA paratransit trips are much more costly to provide than fixed-route trips. Similarly, the average cost of providing an ADA paratransit trip in 2010 was \$29.30, an estimated three and a half times more expensive than the average cost of \$8.15 to provide a fixed-route trip. The average cost of providing an ADA paratransit trip increased 10 percent from 2007 to 2010.

Flexibility and the Role of Technology

Within the DRT system, scheduling and routing is a flexible trait. Having the ability to create different schedules and routes is what makes DRT different from an FRT service. Some DRT services allow scheduling up to two weeks in advance, and some even allow same-day scheduling if room is available. Those DRT services that provide ADA paratransit are required to accept a trip on a next-day basis. Among the added benefits of the DRT system, the flexible scheduling remains essential.

Research conducted by Kai Monast indicated that by applying a “well-planned scheduling structure,” the performance of DRT can be further improved. Similar studies show that implementation of more advanced technologies could improve the DRT system. Kurt Palmer discusses in his research how the advanced technologies have improved the DRT systems’ efficiency. The benefits of these advanced technologies include the response to changed client schedules and improvements to the reliability of trip schedules.

Significance and Performance

Many perceive a DRT system working in only dense areas with a greater number of destinations. However, the TRCP Report mentions that there are a greater number of DRT systems in rural areas than there are in urban settings. The DRT system in rural areas proves useful by helping improve the mobility of many individuals who do not have access to privately owned vehicles.

DRT services in urban areas tend to experience high demand with simultaneously high costs. For example, the urban region of King County, Washington, proved to have low ridership and high operating cost. The DRT performance within urban areas is not as efficient compared to suburban and rural areas because of the traffic congestion and complicated street networks. There also tends to be greater competition in urban areas with multiple services, including buses and taxis. Because there is such a high demand for DRT systems in dense urban areas, studies have been done to improve their efficiency. In Europe, Jenny Mageean argued that by implementing telematics-based DRT, limitations in urban areas could be addressed.

The DRT systems have created better options for rural areas, since most lack any form of public transportation. With greater flexibility, the DRT gives rural populations greater access to medical facilities, which are usually located around urban centers, as access to medical facilities becomes less difficult when the distance is served by the DRT system. Thus, mobility between rural and urban areas is served incredibly well by the DRT system. These rural areas now have a greater amount of accessibility and are able to do so in a shorter time period. With the greater availability of rural to urban transport, communities are provided better accessibility

not only to medical facilities but also to other critical services.

Performance is an important factor to evaluate in DRT to understand what does work and fix what could work better. The performance of DRT systems has been widely researched for the last decade. When it comes to the performance of the DRT systems in the world, many studies have shown that they desperately need improvement. Monast and Joshua Worthy researched the rural DRT system, concluding that it is inefficient to deliver, time-consuming to schedule, and requires a large vehicle fleet. Although there are positive and negative aspects to rural DRT service, helping these communities have greater mobility to “activity sites” outweighs the hardships within the service.

Each study looks at different variables when assessing the performance of the DRT systems. Luca Quadrifoglio's performance measures include total trip miles, deadhead miles, and fleet size, while Palmer includes passenger miles and trips per vehicle as well as operating expense per passenger trip and mile in his performance measurement. Although both look at different variables and find separate results, they both established that there still needs to be further research done to assess the performance of the DRT system. The TRCP report indicates that, because of the growing demand for service, many DRT systems are under pressure to improve their performance. This TRCP report used similar performance measures as did Palmer.

Another factor studied in regard to performance are traffic conditions in urban areas compared to rural areas. In urban areas, there tends to be a great deal of congestion, which impacts the DRT systems' overall performance. Urban and rural areas should have different variables reviewed when assessing performance because they have different factors influencing them. In rural DRT, according to the TCRP, the performance variables should also include deadhead time and miles, which were also included in Quadrifoglio's study on DRT performance. By researching the factors influencing DRT performance, both urban and rural areas can improve their systems.

Environmental Benefits of DRT

The environmental impacts of different road public transport were documented by different researchers, providing a framework for the assessment of

transit's environmental impacts. With the use of DRT systems, the use of POVs will somewhat decrease, and vehicle emissions will be decreased simultaneously as well. Studies indicate that creating better transit scheduling in both FRT and DRT systems will result in fewer environmental impacts. Many of the DRT services, apart from the social and mobility objectives, have environmental motivations. They are meant to reduce the use of POVs and to encourage a modal shift away from the car. In doing so, many agree that DRT is one of the many ways of bringing about a sustainable transportation system.

Demand-Adaptive System

The newer transit system known as the demand-adaptive system (DAS) displays features of both fixed-line bus service and DRT. The DAS bus line has mandatory stops in its schedule, which follows the fixed-line bus service pattern. On the other hand, it also follows the DRT service by giving individuals the option to issue requests for minor detour stops. This DAS service creates strategic plans in the scheduling phase, compared to DRT service in which schedules are created a short period before issuing service. Although DAS provides some flexibility in its service, the DRT still offers the maximum flexibility for users.

Department of Transportation Act of 1966

President Lyndon B. Johnson signed the Department of Transportation Act (H.R. 15963) into law (P.L. 89-670) on October 15, 1966. It was an idea that had taken almost 100 years to turn into reality. Similar attempts to create the department had failed at least 17 times before. The law became effective on March 30, 1967. Upon signing the bill, Johnson noted that by 1966 the transportation sector had become the largest of all American industries, employing millions of people. Creating the Department of Transportation (USDOT) was intended to allow the president to consolidate 35 transportation-related programs that had previously been divided among seven departments and

agencies. Altogether, Johnson predicted that the new Department of Transportation would bring 100,000 employees under the USDOT umbrella and that it would operate with an annual budget of some \$6 billion.

The Department of Transportation Act of 1966 defined the functions of USDOT as modernizing and unifying national transportation policy, promoting safe travel, ensuring that the most up-to-date technology was employed throughout the transportation sector, strengthening partnerships with other levels of government and with the private sector, and improving global transportation links. The Department of Transportation was the 12th cabinet-level department. Alan Boyd, a former chief of the Civil Aeronautics Board (CAB) and the chair of Johnson's USDOT task force, became the first secretary of transportation. The USDOT held the Pageant of Transportation on April 1, 1967, to celebrate its official opening. For the first time in U.S. history, federal oversight of highways, railways, aviation, and maritime operations was consolidated within a single department.

Background

Between 1950 and 1967, responsibility for representing the interests of the transportation sector had resided partly with the Office of the Undersecretary of Transportation, which operated under the Department of Commerce. Oversight of other aspects of the transportation sector was divided among the Department of Treasury, the Department of the Interior, the Interstate Commerce Commission, the Civil Aeronautics Board, the Federal Aviation Agency, and the Saint Lawrence Seaway Development Corporation. When considering all federal transportation responsibilities, highway transportation functions were dispersed among 12 agencies that had been created between 1893 and 1966. Eighteen departments oversaw rail transport functions during that same period. Between 1843 and 1967, 25 agencies held federal responsibility for maritime operations. Aviation functions had been directed by 18 federal agencies between 1926 and 1967.

In addition to these transportation functions, federal responsibility for urban mass transit was divided between the Office of Transportation, Housing and Home Finance Agency and HUD's Urban Transportation Administration. Transportation safety research functions were assigned to

the National Aeronautics and Space Administration (NASA) under the Electronic Research Center (1965–66) and the Electronic Research Center, Office of Advanced Research and Technology (1966–70).

There were many reasons the Department of Transportation was created in 1966 after so many previous attempts to establish a voice for the transportation sector had failed. One was the legislative expertise of Lyndon Johnson, which had been honed by 10 years spent representing Texas' 10th Congressional District in the House of Representatives (1937–47) and 13 years in the U.S. Senate (1948–61). In his 1966 State of the Union address, Johnson had pledged his support for the creation of a national department of transportation.

A second reason that DOT was finally created in 1966 was the conviction of Najeeb E. Halaby (1915–2003) that the time was ripe. Halaby was the Dallas-born son of a Lebanese-Syrian father and an American mother. He had fallen in love with flying as a young man after witnessing a Charles Lindbergh flight. After enlisting in World War II, Halaby helped set up a test-pilot school for the Navy and had flown the world's first combat jet. In 1961, President John F. Kennedy chose Halaby to head the Federal Aviation Administration. In that position, Halaby became frustrated over the fact that transportation was given no voice in the president's cabinet. He was also convinced that the Department of Defense had intentionally shut the Federal Aviation Agency out of policy discussions on supersonic transport. Others who believed that the time had finally come to establish a national department of transportation included Budget Director Charles Schultz, Presidential Assistant Joseph A. Califano, Jr., and Alan S. Boyd, who became the first secretary of transportation.

Other reasons that the time was ripe for passage of the Department of Transportation Act of 1966 involved the growth of the transportation sector in conjunction with concerns over issues caused by that growth. Those issues involved areas such as traffic congestion, crowded air lanes, accidents and safety abuses, outmoded equipment, and inefficient service. By 1965, the American highway system had grown to more than 3 million miles of paved highways and streets, and more than 90 million vehicles traveled those roads. Within the aviation industry, 100,000 airplanes traversed more than a billion

miles. The transporting of freight involved moving 1.5 trillion ton miles of cargo along railroads, highways, and waterways.

Lyndon Johnson had asked Alan S. Boyd (1922–) to chair a task force that was charged with laying the groundwork for writing the law that would create the national department of transportation. Boyd, a lawyer who had served with the Army Troop Transport Command during World War II, had been appointed to the Civil Aeronautics Board by President Dwight Eisenhower in 1959 and had become chief of the CAB under President John Kennedy. In 1966, Boyd was serving as Undersecretary of Commerce for Transportation within the Department of Commerce. The report of the Boyd Task Force was released on October 22, 1965. It called for the creation of the U.S. Department of Transportation and recommended that the Federal Aviation Agency, the Bureau of Public Roads, the Coast Guard, the Saint Lawrence Seaway Development Group, the Great Lakes Pilotage Administration, the Car Service Division of the Interstate Commerce Commission, the subsidy function of the Civil Aeronautics Board, and the Panama Canal be placed under its jurisdiction.

From Law to Reality

By March 6, 1966, the Johnson administration had a bill ready to submit to Congress. However, once Congress began working on the bill, it was significantly weakened from the bill submitted by the president. Nevertheless, some 95,000 employees were ultimately moved into the new Department of Transportation. Most of them worked for the Federal Aeronautics Agency, the Coast Guard, or the Bureau of Public Roads.

The overriding goals of the newly created Department of Transportation were related to safety, consumer protection, planning and research, and coordinating and assisting state and local governments in meeting transportation needs. Section 2 of the Department of Transportation Act of 1966 identified the specific purposes of the new department as coordinating and administering all national transportation programs; facilitating the development and improvement of the U.S. transportation sector; coordinating transportation activities carried out by governments, carriers, and labor; promoting technological advances within the transportation sector; providing leadership for the entire

transportation sector; and advising the president and Congress on transportation needs through policy and program recommendations.

When setting up the Department of Transportation, Alan Boyd immediately began addressing vehicular safety issues. By January 1967, USDOT had issued 21 new motor vehicle safety standards. Two months later, the National Highway Safety Advisory Committee was established to provide advice, make policy recommendations, review transportation policies and programs, and issue reports. Members of the committee included the secretary of transportation or a designated USDOT representative, the Federal Highway Administrator, the National Highway Traffic Safety Administrator, and 35 members appointed by the president. Participation by federal employees was limited to no more than four members. All other members were to be representatives of state and local governments, transportation experts, or transportation-sector owners and officials.

Boyd continued to serve as secretary of transportation until 1969 when Republicans took over the Oval Office following the election of Richard Nixon. During his time in office, Boyd concentrated on issues involving airport modernization, air traffic control, driver education standards, and the reduction of alcohol-related accidents. He also worked with Lady Bird Johnson, the First Lady, on her highway beautification program. Because the needs for federal involvement in mass transit had become so urgent, the Department of Transportation Act of 1966 also included a provision for addressing mass transportation issues. Dissatisfied with the congressional effort, in 1968 Johnson transferred responsibility for overseeing mass transit from the Department of Housing and Urban Development (HUD) to the Department of Transportation. Despite his accomplishments as transportation secretary, Boyd was faulted for failing to revitalize passenger rail service.

In 1970, President Nixon transferred the Electronic Research Center from NASA to USDOT. In 1981, just as Johnson had urged Congress to do in 1966, the Maritime Administration was transferred from the Department of Commerce to USDOT.

It had generally been agreed upon that one of the major functions of the new Department of Transportation should be to oversee the safety of motorists on U.S. roads. According to the National

Highway Traffic Safety Administration, 50,894 people were killed in vehicular accidents in 1966. If nothing were done, the then current rate of 5.5 deaths per 100 million miles of travel was predicted to rise dramatically. In response to these concerns, in 1966 Congress also enacted the Highway Safety Act, which created the National Highway Traffic Safety Administration (NHTSA) as an agency within the Department of Transportation. Assisted by federal funds, state governments were required to work with the NHTSA and USDOT in creating their own highway safety programs.

By 1983, the Department of Transportation Act had been amended four times, but most amendments dealt with language conformity. A 1983 amendment, however, was chiefly concerned with environmental protection. That amendment instructed the secretary of transportation to work with the secretary of the interior, the secretary of HUD, and state and local communities to preserve the environment and historic sites and to protect the natural habitats of wildlife and waterfowl.

The major reorganization of the executive branch that followed the terrorist attacks of September 11, 2001, transferred the Coast Guard and USDOT Operating Administrations (renamed Transportation Security Administration) to the newly created Department of Homeland Security.

Deregulation

Deregulation was a politicoeconomic movement that began in the late 1960s in a drive to undo the regulatory controls on transporting of goods and people. The regulations had been imposed by popular demand to protect the public from rapacious shipping companies since the 1870s. Deregulation decommissioned the regulatory work of a century in order to eliminate its harmful effects. Regulation of shipping tariffs and other features of the transportation industry began in the United States in the 1870s in an effort to prevent overcharging from the public's point of view. The railroads were conducting business in an unregulated market economy, providing services to millions of customers. However, their pricing practices and other customer concerns were often viewed with hostility. In many cases they were charging high freight rates because only one railroad was available for shipping crops or livestock.

Customer complaints were often ignored in an era of ever-expanding trackage hauling ever-growing lots of goods. Politicians responded to the complaints of voters and interests dissatisfied with railroad services by creating the Interstate Commerce Commission (ICC) in 1887. The ICC was supposed to regulate railroad freight rates by fixing

price ceilings in order to prevent the railroads from reaping what would be deemed excessive profits. However, the ICC had little in the way of enforcement power. It was also weakened in its regulatory powers by adverse Supreme Court decisions.

During the administration of President Theodore Roosevelt the Hepburn Act (1906; 34 Stat. 584) was adopted. This act began the expansion of the ICC's authority from regulating railroads to regulating all common carriers except airplanes. The regulatory controls were widened and extended in the period between 1920 and 1940 to other passenger common carriers and to the growing aviation industry. The Motor Carrier Act of 1935 (P.L. 74-255, 49 Stat. 543) was an amendment to the Interstate Commerce Act. It instituted federal regulation of interstate bus lines and airlines as a form of public utility monopoly.

The regulatory power of the ICC was based upon the expressly delegated power of Congress to regulate interstate commerce under Article I, section 8 of the U.S. Constitution. The ICC's regulation of motor carriers was modeled after its regulatory powers over railroads. The legal effect was that the ICC had major economic control of the motor carrier business because its control chose the companies that could be motor carriers, the kinds of services they could offer, and the rates they could charge.

Like the Motor Carrier Act of 1935 the Civil Aeronautics Act of 1938 (CAA; PL 75-706, 52 Stat. 973) was based upon Congress's power to regulate interstate commerce under Article I, section 8 of the Constitution. The CAA created the Civil Aeronautics Authority in order to centralize safety regulations but did so in a way that balanced commercial interests. Key provisions of the act were linked to the authority of the U.S. Post Office to carry the mail. Contracts to carry the mail with airlines were federal issues.

1950s

By the early 1950s the ICC was regulating almost anything considered transportation in the United States. It regulated not only railroad, bus lines, and airlines but also bridges, internal waterways shipping, intercoastal shipping, ferries, and pipelines. However, most of the freshwater barge and boat traffic as well as the truck traffic had been exempted by a variety of laws.

The Transportation Act of 1958 gave the ICC jurisdiction over passenger train service in order to coordinate the ICC's decisions with state commissions that regulated passenger trains. However, the decisions of the ICC under its authority were widely criticized as not rational from a business perspective. Also irritating to many in the public was the very slow pace at which the ICC approved mergers. The repeated failures of the ICC to act in a timely manner ended in serious financial harm and loss of service to the public as some railways failed. But this was of not apparent concern to the ICC. Its overregulation reached the point where it required railroads that were losing money to continue to operate, which deprived them of property without proper due process of law.

1960s and Beyond

In 1962 President John F. Kennedy called upon Congress to address the problem of transportation regulation. In 1966 President Lyndon B. Johnson was able to sign legislation establishing the Department of Transportation. By the late 1960s calls for deregulation of transportation were gaining strength. In the 1970s and 1980s Congress began to pass deregulation laws. The Airline Deregulation Act of 1978 (P.L. 95-504, 92 Stat. 1705) sought to remove the government from control over commercial aviation. The regulatory powers of the Civil Aeronautics Board were phased out so that market forces could affect the airline industry and the prices paid by passengers for tickets. The main regulatory power remaining was that of control of safety standards.

Railroad deregulation began when Congress passed the Railroad Revitalization and Regulatory Reform Act of 1976 (P. L. 94-210, 90 Stat. 31) also known as the "4R Act." Full deregulation came with the passage of the Staggers Rail Act in 1980 (P. L. 96-448, 94 Stat. 1895). The Staggers Act moved to end the regulatory structure that the ICC had built since its inception in 1887. Its provisions included removal of certain regulations so that carriers no longer needed ICC approval to enter into contracts with shippers to set prices and services. The new economic realities were that the railroads were no longer the giants of transportation. The development of the Interstate Highway System had moved millions of people off passenger trains and into automobiles that cruised at speeds as good as those of trains at lower costs. In addition, transfer trucks

were hauling millions of tons of freight that had previously been carried by the trains.

The Motor Carrier Act of 1980 (P. L. No. 96-296, 94 Stat. 793) deregulated the trucking industry. Many new trucking firms were then able to enter the hauling business and to compete. In 1996 President Bill Clinton signed the Interstate Commerce Commission Termination Act P.L. 104-88, 109 Stat. 803). The final act of the commission before its death at the age of 108 was for its chairman to transfer its remaining functions to the new agency, the Surface Transportation Board.

Observers have noted that many of the rules and regulations of the ICC have remained in effect, for example, its loss-claim procedures. In addition, its orders, rules, permits, and much more are still law. The reason for deregulating the transportation industry was to allow for greater competition. It was believed that more competition would stimulate more productivity, efficiency, and lower prices. For airlines, the value of the companies went down drastically as many in the competitive struggle went bankrupt. The costs that drove them down were often related to fluctuations in fuel prices due to political forces beyond their control and to labor costs that had developed when the industry was regulated.

Deregulation has been beneficial to many consumers and to some firms seeking to enter the transportation business. However, for many companies the results have been economically unfavorable.

Derived Demand

Derived demand is the demand for an intermediate good (or service) that results from the demand for or provision of another good (or service)—such as the demand for vehicles, gasoline, and parking spaces that occurs in order for people to enjoy time with friends, get food shopping done, sell their products in town, or supply their labor to employers. W. J. Baumol and A. S. Blinder provide the example of demand for fertilizer as derived from the underlying demand for corn, the final product. An increase in the demand for corn drives up corn prices, which drive up the marginal revenue product (MRP) of—and therefore demand for—fertilizer.

Transportation is largely a derived demand because its pursuit stems from a desire to engage in other activities. Generally, travel loses its value without the activities at the trip's origin and destination. Often modeled as a “dis-” utility or cost of engaging in the activity of interest, travel costs rise with travel time and trip expenses. Travel time has great value, and travel time savings typically constitute the greatest share of benefits that emerge from transportation system improvements. What differentiates transportation from other intermediate goods with derived demand is that it is not a stand-alone final product or service. “Unused” transportation

movements (for example, underutilized highway capacity at a specific time and place or unsold seats on a flight) cannot be stored for use at a later time.

J.-P. Rodrigue et al. defined two types of transport-based derived demand. Direct derived transport demand directly results from activities. For example, in the case of employees commuting to work, the demand for transportation between residences and workplaces is a direct result of supply (households) and demand (employers) for labor. In freight movements, travel is a derived demand resulting from a supply chain moving other intermediate and final goods, such as raw materials, parts, and finished products. Indirect derived transport demand results from other transportation demands (which presumably are derived themselves from nontransport activities). For example, demand for roadside assistance (of a tow truck or emergency vehicle) results from the travel demand of the vehicle requiring assistance. In freight movement, warehousing demand can be considered an indirect derived demand, since it only exists as a result of differences between commodities available where they are produced and where they are consumed.

Interestingly, some relatively recent studies have challenged the conventional idea of travel as a derived demand. P. L. Mokhtarian and I. Solomon provide conceptual and empirical evidence to

While transporting workers in Santa Clara County, California, the Altamont Commuter Express passes through this portion of the Don Edwards San Francisco Bay National Wildlife Refuge. A survey of nearly 2,000 San Francisco Bay Area residents found that a certain amount of commuting time was actually valued by many respondents, which contradicts some assumptions about derived demand. The average ideal commute time for respondents was 16 minutes; only 3 percent preferred a commute of 0-to-2 minutes.

highlight examples of undirected travel—like “joy rides,” recreational boating, biking for exercise, and running races. These are activities where travel/movement is the desired product, without any meaningful origin or destination. The researchers also propose that human desire for variety and curiosity may lead travelers to seek destinations (and routes) that are not necessarily the closest (shortest) in distance or least expensive to access. They argue that travel should not always be viewed as a disutility, due to some travelers’ penchant for travel itself and the various valuable activities that can be conducted during travel, including enjoyment of music or news while driving, reading while riding on transit, and the health benefits of biking and walking. In a survey of almost 2,000 San Francisco Bay Area residents, Mokhtarian and Salomon found evidence of affinity for extra travel (such as for long-distance as compared to short-distance travel, for entertainment-related travel over less discretionary/more mandatory travel, and for travel by plane over car travel). The average reported ideal commute time was 16 minutes, with only 3 percent of respondents desiring a 0 to 2 minute commute, indicating that some non-negligible commute time or at least some distance from work is of value to many.

In the freight regime, Rodrigue noted how operational scale rewards large distribution systems, centered on hub nodes that become more important than the origins and destinations themselves, as freight volumes increase. The derived demand for freight transportation becomes less related to the locations of product supply and demand as supply chain systems grow larger and more complex, challenging traditional notions of derived demand as transportation costs become embedded in supply chain costs. Finally, as transportation costs and inventory levels have fallen, thanks to just-in-time manufacture and delivery, travel delays cause significant disruptions to inventory maintenance, rendering travel time reliability at least as important as freight travel time itself.

A similar story can be told for personal travel, where value of reliability (VOR) is typically measured as the standard deviation in travel times on a set route at a given time of day. Using data for travel on the variably tolled SR-91 in Southern California, D. Brownstone and K. A. Small estimated travelers’ VOR to be \$12 to \$32 per hour of standard deviation in arrival time, or roughly 95 percent to 145

percent of the corresponding value of travel time (VOTT) on those links.

Conclusion

In summary, travel has traditionally been considered a derived demand, a by-product of other (typically economic) activities occurring at trip origins and destinations. Travel itself has been viewed as a disutility and cost, only demanded due to the desire for other goods and services. However, many contrary examples exist, in both the passenger and freight sectors. For example, leisure travel—where either the travel itself or concurrent activities performed while traveling provide value to the traveler—is not so clearly a derived demand. On the freight side, as distribution systems grow larger and more complex, travel costs becomes endogenous to the design of the supply chain system, with intermediate nodes (“hubs”) playing a more significant role in determining movements than product origins and destinations.

Destination Choice Models

A destination choice model is an econometric model that can be used to understand and predict the choice of trip destination, or in other words, the choice of activity location at the destination end of a trip. They can be used alone or as part of a regional travel demand model system. For instance, the trip distribution model in a four-step Urban Transportation Modeling System (UTMS) could be represented by a destination choice model when the analysis is undertaken at the disaggregate level. (A UTMS could operate at the aggregate level of trips between zones or at the disaggregate level of trips made by individual travelers.) Destination choice models can also be used to predict the locations of activity stops in an activity-based transportation model and are referred to as location choice models in this context. The analysis of short-term mobility behavior, in the form of daily activity and travel patterns, is thus the primary purpose of destination choice models.

The choice of destination is typically a specific building (for example, work or restaurant location) or a set of buildings (for example, a shopping complex or area). However, for transportation planning purposes, destination choice models usually operate with zonal choice alternatives, which are spatial clusters of elemental alternatives. The study area is divided into zones, for instance, transportation analysis zones (TAZs) or census divisions (tracts, blockgroups, blocks), which are described by attributes such as area, population, accessibility, land use composition, distance from the individual's home or work locations.

The zonal approach is preferred because (1) the use of elemental destination alternatives would impose a much larger computational burden, (2) data is rarely if ever available at the elemental level, and (3) for transportation planning, the desired objective is the prediction of trip interchanges between zonal pairs. While zonal destination choice models are the norm, improved computational capacity in recent times has meant that analysts can define smaller zones. Accordingly, the most spatially detailed models today operate on parcels. (A "parcel" is a land area that is managed as a single, relatively large unit, defined either to consist of a single land use or based on ownership;

parcels could often, though not always, correspond to elemental destination choice alternatives.)

Model Structure and Calibration

Destination choice models are usually designed as random utility maximization (RUM)-based discrete choice models, where individual i is assumed to gain a stochastic utility U_{ij} from zone j as shown in the equation below:

$$U_{ij} = V_{ij} + \epsilon_{ij}$$

where V_{ij} is the deterministic component of the utility and ϵ_{ij} is a random (stochastic) error term. The deterministic component of the utility is hypothesized to be a function of observable attributes X_i , Y_j , and Z_j , for example:

$$V_{ij} = f(X_i, Y_j, Z_j, \theta)$$

where X_i is the vector of individual socioeconomic attributes (such as age, gender, employment status, income, possession of drivers license), Y_j is the vector of attributes of the zonal alternatives that are indicative of size (such as area, population, number of employees by occupation type), Z_j is the vector of nonsize attributes of the zones (such as accessibility, distance from the individual's work or home location), and θ is the vector of parameters to be calibrated (estimated). Different assumptions on the distribution of the stochastic error term lead to different model structures and corresponding formulations for the probability that individual i chooses destination j . The simplest of these is the multinomial logit model of destination choice.

The parameters of the destination choice model are usually calibrated using data gathered from travel diaries (for example, the National Household Travel Survey in the United States) or activity diaries (for example, the Mobidrive data in Germany) that can be used to link an individual's revealed choice of destination with observable attributes of the individual and the destination alternatives available to him/her. Since the number of zones in a region can be quite large, sometimes in the thousands, a common practice in model calibration is to draw a subset of alternatives from the universal choice set for each trip in the travel diary data set.

Discrete choice models are typically calibrated using maximum likelihood estimation techniques,

and can be estimated using standard software such as Biogeme, Alogit, and NLogit or by developing specialized code in software such as R, Matlab, Gauss, and Ox.

The Accessibility Measure

Accessibility measures are used to characterize the land use and transportation system configuration of a study area and form an important element in destination choice models. Accessibility measures commonly have two key components: the impedance factor, arising from the need to travel a non-trivial distance to the destination and exerting a damping influence on the attractiveness of the destination, and the destination factor, which is related to the characteristics of the destination and the level of opportunities available at the destination to address the needs of the individual (number and quality of shops, for example). Characteristics of the individual also affect the degree of accessibility enjoyed.

Application for Planning and Policy

Destination choice models are estimated usually for one of two purposes. One is to predict the demand for transport services arising from individuals' choice of location (or destination) for activity participation within long-term planning contexts. Therefore they form one of the steps in a UTMS or activity-based model, where they are usually implemented using simulation methods. For this purpose, it is necessary to ensure that the explanatory variables included in the destination choice model can be easily projected for future planning horizons. Moreover, the role of the destination choice model in such long-term planning contexts is to spatially peg the predicted travel demand, and therefore accuracy of prediction is a key factor in the development of these models.

The other use of destination choice models is to understand the drivers of location choice so as to influence policy in the short to medium term. For instance, will congestion pricing lead to a change in spatial travel patterns and, if so, how and to what extent? What role does travel time and cost play in the choice of location for activity participation? Clearly, this will vary depending on purpose, with work location remaining fairly inflexible in the short term and shopping location potentially being very dynamic and flexible.

Simultaneity in Decision Making

The primary decisions that individuals make to participate in activities separated over space are the location of activity participation, the choice of the mode of travel, the time of day of travel, solo versus joint travel, route choice, and the choice of trip chaining. The order in which these decisions are made is unknown to the observer/analyst and there has been no conclusive proof that any particular sequence of decisions is more likely than the other. It is important to keep this in mind while developing a destination choice model, since one or more of these decisions may be correlated with the choice of activity location.

Modifiable Area Unit Problem

The modifiable area unit problem (MAUP) refers to the statistical biases that arise due to the definition of zones, which are only aggregations of the real elemental alternatives. These biases arise from (1) a scale effect (that is, the extent of aggregation; for example, parcels versus census districts), and (2) a zone effect (that is, the shape of the zone; for example, 1 mile square versus circle of radius 1 mile). Because of MAUP the same basic data can yield different results when different zonal configurations are used. While there are no solutions to this problem, it is good practice to try different zonal configurations to test the robustness of model results.

Spatial Correlation and Heterogeneity Effects

Destination choice models, being essentially spatial models, suffer from the inherent complexities of spatial econometrics. A few of these issues are briefly discussed below.

The unit of choice for activity location decisions is not well defined. Take for instance, a shopping trip. An individual could choose to visit a specific store, a shopping mall, or a shopping district.

Activity location decisions usually involve a very large set of possible alternatives regardless of the spatial definition of the alternative. Even if the unit of choice is a zonal aggregate of shopping opportunities, the potential choice set would include all the zones in the planning region, which is still a large number (typically in the hundreds).

Due to the continuum of space, the various destination choice alternatives are likely to share common attractiveness factors (spatial correlation). For instance, we would expect zones that are nearer

each other to be more substitutable than zones that are far apart.

In addition to spatial correlation, spatial competition or agglomeration effects are also likely to play a role. Some alternatives benefit from being close to other similar alternatives (agglomeration effect) as in a shopping district, while some alternatives benefit from being away from other similar alternatives (competition effect) by capturing the market in their immediate neighborhood.

The development of an operational destination choice model usually involves some level of spatial aggregation of decision makers (individuals or households into neighborhoods or zones) and elemental units of attraction (stores or parks into zones), which ignores potential heterogeneity within the zone.

Complex model structures are needed to capture these various effects and to reduce the potential bias arising from ignoring them.

Unobserved Factors of Heterogeneity

The extent of heterogeneity in destination choice depends on the level of flexibility in the activity participation, with generally high levels of heterogeneity observed in the case of nonwork travel. The heterogeneity in choice behavior could be interpersonal or intrapersonal, and it could be due to observed or unobserved factors (from the analyst's viewpoint).

Interpersonal heterogeneity in destination choice could be a result of observed factors such as income or unobserved factors such as habit persistence. Two individuals identical in every respect may still choose different locations if one of them exhibits habit persistence or loyalty.

Intrapersonal heterogeneity in destination choice could also be a result of observed or unobserved factors. Observed factors such as the time of day may constrain an individual to choose a closer shopping location on a weekday, whereas the individual might prefer a different, more distant shopping location in the absence of time constraints on the weekend. Unobserved factors such as variety-seeking or boredom may also result in the individual selecting different shopping locations on consecutive choice occasions.

There are many such possible sources of unobserved heterogeneity, and it is important to identify and include all these within the conceptual framework for destination choice models. Omitted

sources of heterogeneity in choice models usually result in underspecified models, and in such situations a good conceptualization can help correctly interpret such models.

Dial-a-Ride

Demand-responsive transit (DRT) is also called demand-responsive transport, demand-responsive service, flexible transport services, or paratransit, but is most commonly known as Dial-a-Ride. In many localities Dial-a-Ride is called DART for Dial-a-Ride Transit. Whatever name is used it refers to an advanced public transport system that is user oriented. DRT is a flexible routing and scheduling system for small or medium vehicles that are engaged in sharing rides between pick-up and drop-off locations. The pick-ups and drop-offs are made to satisfy passenger needs.

DRT systems are operations with vehicles that respond to calls from passengers or their agents. A call must be placed to the DRT transit system operator. The transit operator then dispatches a vehicle to pick up the passenger in order to transport him/her to the desired destination. The system is characterized by having vehicles that do not operate over fixed routes. Nor do DRT system vehicles operate

A Dial-a-Ride van between runs in the city of York in the United Kingdom in April 2012. While private companies run some commercial services, such as airport and casino shuttles, most Dial-a-Ride routes are community not-for-profit enterprises.

on fixed time schedules, although there may be temporary situations in which a vehicle follows a schedule. Typically, the vehicle carries several passengers who are going to different locations from different pickup points. Their journey may be interrupted if new calls come in that require the driver to deviate from the planned route in order to accommodate the latest passengers to call for service.

DRT systems have been instituted in many rural areas in order to provide transport services. DRT systems are also used in areas where regular bus service is not profitable because of low demand. Funding for DRT systems may come from a local transit authority as a subsidized socially necessary transportation system. In cases where DRT is subsidized, operators may be chosen by auction or by submitting sealed bids for the right to be the transport provider. Regardless of the selection mechanism used, the transport operator is given a monopoly for DRT services it provides.

A DRT system gives people access to transportation that gets them to places and events in the community. It provides a means for people to get to appointments, activities, and social events. Trips to health care providers, places of employment, shopping centers, senior centers, education centers, or recreational places are available in a timely manner. The system is designed for people whose access to transportation or whose physical mobility is limited due to health problems. Such physical challenges

may make it difficult for people to use a regular fixed-route bus service even if it is available. What a DRT system offers is a special transportation service that is much better suited to those with a disability, providing, for example wheelchair-equipped vehicles.

Many DRT systems are funded by the local transit authority. Some are self-funded. Most are a community service that is a not-for-profit enterprise. Other DRT systems are funded by private companies for commercial reasons, such as providing customers a ride to their businesses. This may be similar to casinos providing gamblers with a ride to and from home. Some bus companies have set up DRT programs that service airports. In some cases the DRT program may compete with private for-hire shuttle bus companies.

Bus companies typically operate on fixed routes that provide transportation at approximately the same time for specified locations. Drivers must maintain the route and may not deviate from it without the likelihood of significant consequences. If special circumstance such as a matter of safety warrant the driver may deviate from the route, but in general it is not permissible for the driver leave the vehicle's assigned route.

Types

If a system is modified it can be a "deviated" fixed-route service system. In such a case the transportation service moves along a fixed route at generally fixed times. However, if the transit system is a deviated fixed-route system then the bus driver, transporter or transit provider may deviate from the assigned route in order to pick up or drop off passengers who ask for the deviation.

In contrast, a DRT system has entirely flexible routes and schedules. Shuttle bus services move between fixed locations at fixed times; DRT systems do not have fixed departure and arrival points. Other forms of DRT include paratransit services. This is a service not available to the general public. It is for qualified users who are generally people with disabilities, the infirm, or the elderly.

Share taxicab is a DRT service that is prebooked. It allows users to share taxis services when opportunities allow for such collaboration. However, a DRT taxicab share system means multiple people may be going to different locations. This may mean that a rider may be the last to be dropped off even if this creates an inconvenience.

Operations and Benefits

DRT systems operate in a defined zone rather than a defined route. The journeys begin and end inside the zone. A fixed bus route is normally unalterable. A DRT journey may be fully freeform. Some DRT systems have a skeleton route with a probable schedule. However, the journey and the schedule will vary as needed. In order to be picked up, a rider makes a call to make an appointment for pickup at some location at a time that will likely be approximate rather than fixed.

Some DRT systems may have defined termini. These will be at the two locations that can be used as a route. Locations may be an airport, a transportation exchange point, or some other location.

In order to ride on a DRT system, passengers must call a central dispatcher and request a booking for a ride. The dispatcher will inform the potential rider of the options available for pick up and the closest destination point. To connect riders and vehicles, DRT systems are using fleet telematics technology. Telematics use integrated telecommunications and informatics to track and control vehicles on the move. Global positioning systems are also integrated into computers along with automotive navigation systems. When used in road vehicles, the systems become vehicle telematics. Using fleet telematics, DRT systems can schedule and dispatch vehicles very quickly. Operators can learn their new passenger pickup points and also be assigned the shortest or quickest route to take to the newly booked passenger.

Vehicles used in many DRT systems are small minibuses due to the low ridership. However, they can also be used to provide door-to-door services for those needing paratransit. In addition, minivans can easily travel down most residential streets. In some DRT systems a passenger may be picked up or delivered by a taxicab hired by the DRT because it is cheaper or because the pickup or destination is not easily reached by the normal DRT vehicle.

Studies of the impact of DRT systems have found that their services can reduce negative health effects and have a positive economic impact. In addition, they have a positive environmental impact and reduce the volume of traffic that would be on the street if everyone were using private or mass transportation.

Common carrier systems often have a legal monopoly to operate over assigned routes. They are

duty bound to pick up all passengers in common. In addition, taxicabs have to get licenses to operate as a kind of common carrier. In contrast, DRT systems use flexible rather than inflexible routes. New kinds of legislation or the amendment of older laws has been necessary to establish the legal authority for them to operate. Disputes have arisen between DRT systems and taxi companies or bus companies when DRT operators pick up passengers who have not been pre-booked. The dispute is over licensing issues. In addition, the kind of license a transport company has may also affect its tax and fuel bills.

Among the benefits of DRT systems is the provision of transportation to those who may be unable to easily obtain it. Also, there is increased passenger throughput, increased road capacity as other vehicles are not needed, and thus lessened vehicle demand. The DRT system has also proven valuable to many employers because it provides a way for some workers to get to their jobs, or to move between work sites.

Diesel Engines

The diesel engine was invented in 1893 by German engineer Rudolf Diesel (who also designed a solar-powered engine that used solar-heated air). Unlike gasoline-powered internal combustion engines that ignite a mixture of fuel and air using a spark plug, the diesel engine is an internal combustion engine that compresses its fuel in order to generate heat to ignite it. As a result, it has the greatest thermal efficiency of any type of combustion engine. The diesel engine was originally designed to replace the steam engine and is the ideal type of engine for large ships, but it has also been used in construction equipment, trains, aircraft, and motor vehicles.

In the United States, diesel engines are especially likely to be used in large vehicles like trucks; diesel engines also have a long history of being used in smaller cars by European manufacturers, such as Volkswagen. Diesel engines are used in about half of the cars in the European Union (EU), where cars are typically smaller than in the United States and large vehicles like suburban utility vehicles (SUVs) are rare. Diesel engines have also been the standard engines for tractors and construction equipment ever since Caterpillar first made diesel tractors in the 1930s, and often they are used to power backup generators deployed during electrical power failures.

Diesel engines offer a number of advantages over gasoline-fueled internal combustion engines. Diesel fuel is easier and cheaper to manufacture, as it is a direct distillation of petroleum, whereas gasoline is processed in more stages. Diesel engines are one and a half times as efficient as gasoline engines, so they use less fuel and they produce less waste heat. The engines themselves are sturdier and have a much longer life span than gasoline engines, which wear out relatively quickly, especially in large equipment where the workload is significant.

The lack of an electrical ignition system makes diesel engines more reliable in damp environments like those of ships, submarines, and construction equipment. Diesel engines are generally more reliable, not requiring the use of high-voltage ignition systems or emitting radio frequencies. As a result of their efficiency, they run cooler than other engines and last about twice as long on average due to stronger engine parts, better lubrication, and less waste heat.

Further, unlike gasoline engines, which must be adapted to use other fuels or fuels with significant additive levels, diesel engines can run on synthetic diesel called biodiesel with no adjustments. Biodiesel is a diesel fuel derived from nonpetroleum sources, which many feel is more sustainable and which has the potential to be more price stable than any petroleum fuel.

The major disadvantages of diesel engines are their emissions and their response to cold weather. Diesel engines have difficulty starting in cold weather because the compression may not generate sufficient heat to ignite the fuel in the ignition chamber if the cold cylinder block and cylinder head absorb it. In diesel-powered emergency generators, this is typically overcome through the use of heaters that prevent the engine parts from becoming that cold. In very cold weather, diesel fuel can also solidify, resulting in a buildup of diesel crystals in the fuel line and eventual engine failure. This is rarely a problem with modern diesel engines except in the coldest regions of the United States, where gas stations offer winterized diesel that gels at a lower temperature.

Diesel exhaust is a serious source of pollution and has been identified as a risk factor for both lung cancer and bladder cancer, as it contains numerous toxins. The fine-particle content is especially high and dangerous, consisting of metallic abrasion particles, sulfates, silicates, soot, aerosols, and ash particulates, though modern diesel engines are much cleaner than the engines of previous decades. Even so, diesel engines produce a large amount of nitrogen oxides, which contributes to smog, and modern emissions regulations require diesel engines in on-road vehicles to reduce this quantity, typically through selective catalytic reduction. Diesel exhaust also contains sulfur dioxide, which precipitates back to the ground as acid rain.

Groups regularly exposed to diesel exhaust and diesel particulate matter include railroad and mine workers, truckers, bus drivers, and children taking buses to school—the last group being one for which the U.S. Environmental Protection Agency (EPA) has shown recent concern. The Clean School Bus USA initiative is a public–private partnership seeking to reduce the exposure of children to diesel particulate matter. Exposure to diesel exhaust can lead to headaches, dizziness, light-headedness, respiratory difficulty, and nausea, with long-term exposure

leading to chronic illnesses of the heart and lungs. Eighteen carcinogens have been identified in diesel exhaust, in addition to other toxins and substances that contribute to birth defects.

Diesel locomotives and boats are considered among the worst sources of dangerous air pollution, in large part because EPA regulations for these vehicles have typically lagged behind those for road vehicles. For instance, while Tier 3 standards for nitrous oxide were eventually adopted for nonroad/off-road diesel engines in 2004 (which made them similar to the standards required for road vehicles), Tier 3 particulate-matter standards for nonroad engines were never adopted. Tier 3 standards for locomotives were not even signed until 2008 and did not take effect until 2011 or 2012. Stricter emissions standards for road vehicles have put locomotives and ships on the path to becoming the largest source of vehicle pollution. A 2006 report blamed such exhaust for 4,000 deaths a year in the United States, as well as thousands more heart attacks and asthma episodes, and a serious economic impact in the form of missed work. The 2006 Environmental Defense report on diesel locomotives, titled "Smokestacks on Rails," drew a comparison with old preregulation factory smokestacks.

Although the Occupational Safety and Health Administration (OSHA) has not established standards specific to diesel exhaust as a unique hazard, the components of diesel exhaust are included in standards related to general industry (specifically, in Part 1910 Subpart N, Materials Handling and Storage; and Part 1910 Subpart Z, Toxic and Hazardous Substances) and shipyard employment (Part 1915 Subpart Z, Toxic and Hazardous Substances). Federal inspection procedures for the Hazard Communication Standard (HCS) also touch on components in diesel exhaust. The Mine Safety and Health Administration (MSHA), which governs the mining industry, does institute regulations for diesel-powered equipment, diesel particulate matter, and diesel exhaust, while the EPA regulates emissions standards for various diesel vehicle types.

California, which is historically an early adopter of environmental regulations that are eventually adopted by the rest of the country, instituted stricter diesel regulations in 2008, requiring heavy-duty trucks and buses using diesel engines—which typically are held to more lenient standards than automobiles—to reduce their diesel particulate

An engineer at the U.S. Department of Energy's Argonne National Laboratory at work transmitting images of emissions from a Mercedes-Benz diesel engine to a computer in 2009.

matter. California has also operated the Carl Moyer Program since 1998, providing funding to retrofit engines in order to achieve better-than-required low emissions levels.

The aforementioned Clean School Bus program is one of several programs included in the EPA's National Clean Diesel Campaign (NCDC), which focuses on reducing the harmful content of diesel emissions. Clean School Bus provides strategies for school districts to reduce the emissions of older diesel buses, which are not required to follow the same emissions standards as new buses. Because of the durability of diesel engines and the budgetary concerns of school districts, these buses can remain in use for a long time, slowing the effects of emissions-standard regulations.

In addition to providing funding to reduce emissions in existing engines and to replace the oldest buses in a school's fleet, the Clean School Bus program encourages bus operators to reduce idling the motor, which needlessly contributes diesel exhaust to the atmosphere. Idling reduction is also policy in many public and private transit companies; frequently bus

stations limit idle time to five minutes, at which point if the bus does not depart, the driver must turn the engine off until time of departure. Other programs in the NCDC are the Ports and Marine program, which seeks to reduce diesel exhaust at ports for better air and water quality; Clean Construction, which provides funding to replace old construction equipment and reduce the emissions of existing engines; the SmartWay Transport Partnership, which seeks to improve supply-chain efficiency in order to reduce emissions of cargo transport and long-haul truckers; and Clean Agriculture, which provides funding to reduce emissions by agricultural equipment.

Diesel Fuel Vehicles

Diesel fuel, distilled from petroleum, is used to power many vehicles today, including passenger cars, buses, and trucks. While older diesel-powered vehicles produced relatively large amounts of air pollution, including particulate matter and greenhouse gases, modern diesel vehicles include a number of devices that reduce emissions and are engineered to run only on ultra-low-sulfur diesel (ULSD); this combination has reduced the amount of harmful emissions from diesel vehicles by about 90 percent.

Diesel Engines

Traditionally, diesel engines have been used in situations where a high degree of power was needed,

for instance, to power large buses and trucks, trains, large ships, and construction and mining equipment. Today, diesel engines are also commonly used in automobiles in some countries, and modern diesel engines are much cleaner and quieter than their predecessors.

Diesel engines operate by internal combustion to drive pistons connected to a crankshaft that transmits their motion to drive the vehicle's wheels. However, unlike gasoline engines, diesel engines do not need spark plugs to set off the explosions that create this motion. Instead, a diesel engine operates at a sufficiently high temperature that the air in the engine's cylinders ignites spontaneously; for this reason diesel engines are sometimes called compression-ignition engines. Rudolf Diesel, a 19th-century German engineer credited with inventing the engine that bears his name, correctly predicted that this higher concentration of oxygen would lead to greater efficiency in diesel as compared to gasoline engines.

Diesel Passenger Cars and SUVs

Diesel cars are common in some European countries but less common in the United States. However, diesel cars and sport utility vehicles (SUVs) are becoming more common in the United States, with a 24 percent increase between 2010 and 2012, from 640,779 registrations to 796,794; there are also about 6 million commercial diesel pickup trucks and vans in use in the United States. However, they still represent only about 3 percent of the U.S. market. From 2010 to 2012, the growth in registrations of diesel cars and SUVs was highest in California (55 percent), Massachusetts (45 percent), and New York (43 percent).

Three factors are believed to suppress the growth of diesel cars and SUVs in the United States: a limited range of models available, the higher cost of diesel vehicles (on average, several thousand dollars more than similar gasoline-powered vehicles), and the higher price of diesel fuel compared to gasoline (on average, about 10 percent higher, according to the U.S. Energy Information Administration). As of 2013, 27 diesel cars and SUVs were available in the United States, but this number is predicted by the Diesel Technology Forum to more than double by 2015. One reason diesel vehicles are increasingly attractive is their higher fuel economy (20 to 40 percent higher than equivalent gasoline engines), which helps

manufacturers meet increasing Corporate Average Fuel Economy (CAFE) standards.

In 2012, over half (54.9 percent) of vehicles registered in the European Union (EU) were diesel powered, a slight decrease from 2011 (55.2 percent), but a substantial increase from 2000, when diesel vehicles represented 31 percent of new passenger cars; since 2006, diesel-powered vehicles have represented more than half of all new passenger vehicles registered in the EU.

In 2007, the EU adopted a comprehensive strategy to reduce carbon dioxide emissions, setting a standard for new diesel vehicles of 130 grams of carbon dioxide per kilometer by 2012, and began enforcing mandatory emissions targets in 2012; if a manufacturer's fleet does not meet the target, it must pay a premium for each new car registered. The emissions standards have successfully reduced average carbon dioxide emissions from new cars (all fuels)—132.2 grams of carbon dioxide per kilometer, down from 135.7 grams per kilometer in 2011. Looking just at diesel cars, average carbon dioxide emissions were 131.6 grams per kilometer in 2012, down from 134.7 in 2011, and a substantial reduction from 2010, when the average was 160.3 grams per kilometer.

Diesel Trucks

Diesel trucks are major contributors to pollution from diesel exhaust. In January 2001, the Environmental Protection Agency (EPA) finalized the Heavy-Duty Highway Diesel rule, setting emissions standards for heavy-duty diesel trucks and buses to take effect in 2007. To meet these requirements, petroleum refiners began producing ultra-low-sulfur diesel in June 2006; ULSD reduces sulfur content in highway diesel fuel by 97 percent—15 parts per million (ppm) versus the old standard of 500 ppm. In addition, diesel vehicles equipped with the advanced pollution control technology necessary to meet the 2007 standards came onto the U.S. market in fall 2006, and these vehicles run only on ULSD. Trucks with the new pollution control devices and running on ULSD produce 90 percent less pollution than previous models. The 2007 standards were projected to reduce particulate matter in exhaust by 110,000 tons per year and to reduce nitrogen oxide emissions by 2.6 million tons per year. Older diesel engines can also run on ULSD, and as of 2010, only

ULSD has been available in the United States as a highway diesel fuel.

Diesel School Buses

Protecting children from diesel exhaust is a particular concern because children have a faster breathing rate than adults, taking in about 50 percent more air per pound of body weight than do adults, and because many school buses are diesel powered. However, children's exposure to harmful emissions has been greatly reduced due to improvements in technology and more stringent regulations: the EPA estimates that school buses built today are 60 percent cleaner than those built before 1990.

The EPA's Clean School Bus USA Program, launched in 2003, offers incentives to reduce emissions from school buses by providing information about retrofit technologies (e.g., particulate matter filters, oxidation catalysts) to make old buses run cleaner, providing funding and incentives to replace or retrofit diesel buses, and providing educational materials and tools to help calculate potential emissions reductions and promote practices that reduce emissions, such as reducing bus idling, switching to cleaner fuels (for example, biodiesel), and using the cleanest buses in a fleet on the longest routes. As of 2012, an estimated 45,000 school buses serving over 3 million students were using technologies that reduce diesel emissions.

Air Pollution

Diesel engine exhaust is made up primarily of gases and soot. The gases include carbon dioxide, carbon monoxide, sulfur oxides, nitric oxide, nitrogen dioxide, and polycyclic aromatic hydrocarbons and other hydrocarbons, while soot is particulate matter including carbon and other organic materials and metallic compounds. Exposure to diesel engine exhaust is associated with elevated rates of many health problems, including heart disease, cancer, asthma and other lung conditions, and eye irritation.

Most exposure to diesel engine exhaust comes from breathing, and exposures are highest among those working around automobiles, trucks, and heavy machinery (drivers, toll collectors, garage employees, etc.), and some farm workers and miners. People living and working near major highways may also experience high exposure, as may children who ride diesel-powered buses to school.

There are many complications involved in studying the health effects of exposure to diesel engine exhaust—the level of exposure is difficult to measure, other exposures may produce similar effects, the effects of exposure may not be apparent for years, and changes in diesel technology mean that the effects of a given amount of exposure in years past may not be equivalent to the same amount of exposure today. However, the International Agency for Research on Cancer of the World Health Organization classifies diesel engine exhaust as a human carcinogen (cancer-causing agent), while the EPA classifies it as a potential human carcinogen. Lung cancer is the disease most convincingly linked to exposure to diesel engine exhaust, with most studies involving occupational exposure (truck drivers, railroad workers, miners, etc.). Some studies have also found relationships between exposure to diesel engine exhaust and cancers of the blood, stomach, bladder, esophagus, and larynx; however, the evidence is not conclusive.

Disabled Driving and Vehicle Modifications

Disabled drivers who have a vehicle of their own are more self-reliant than those having to wait for the availability of another person to drive them, and this can have a significant impact on quality of life. Careful examination of the ability of people with physical abilities to drive personal automobiles has been taking place for many decades—almost as long as attempts have been made to create self-driving cars, which, of course, are designed to need no input from designated drivers at all. These examinations have incorporated examination of the interaction between new technologies and designs and the types of physical disability involved.

Increasingly, the technology embedded in personal therapeutic devices is able to bring the person involved to the level of being able to operate an unadjusted personal vehicle. However, the variety of possible disabilities (which often, of course, come in combinations) and their interaction with the types of personal automobiles and their devices is so great that it can be dangerously reductive to try to make simple principles and rules. Input devices, in particular, have moved to become voice activated or responsive to contact in ways that are nonstandard in previous forms of vehicle control, and these systems do not require the standard driving activities at all. New generations of video games have regularly featured the control of complex machines and vehicles through a variety of joystick and push-button controls and, while it is problematic to project video game representations of life onto the real world, these designs are being introduced into vehicles controlled by disabled drivers. Finally, since it has become evident that vehicles are more safely guided by autopilot systems than by human beings in most circumstances, the degree and nature of any disability has become less relevant as technology

replaces human agency, within the constraints of what is acceptable in society.

Social Norms

To a certain extent, the degree to which vehicles for disabled drivers have become prevalent and acceptable in different countries depends on the attitude of society as a whole toward disability and to different forms of society. Although societies have generally become more internationalized and global norms have started to replace local norms in a number of cases, it nevertheless remains the case that most societies have a definite response or set of responses to an issue such as personal disability. The possible responses can vary along a scale that, at one end, now less commonly seen, requires people to be sequestered at home because of some form of societal taboo, to the other end at which all individuals are fully integrated into the public and private spheres of society. Plainly, this scale is correlated with the ability of disabled people to obtain the modified equipment they need and use it when required.

An additional societal dimension to consider is the attitude toward the welfare state. Since many people with disabilities have difficulties obtaining well-paid work, they may face financial hardship unless they are supported to some extent by the state, since the state is generally required to make transfers universal rather than on a preferential or partial basis, which is what occurs with charitable giving. The state may provide a modified vehicle directly or at a subsidized price or else offer help in modifying standard vehicles according to specific needs. State provision is likely to be integrated with the system of traffic safety and regulations and, hence, to conform directly to legal and insurance requirements. This may not be the case with privately provided modifications.

Forms of Modification

Vehicles are customarily operated with the hands, for the steering wheel and dashboard controls, and with the feet, for using the pedals. Additionally, of course, vision is required to observe conditions through the windshield and windows and also to monitor the various mirrors employed. Nearly all of these requirements can be adjusted or removed through the use of engineering. Hand controls can replace some foot controls and vice versa, while use

of mirrors can assist people with limited neck or spine mobility. Some vehicles make it convenient for wheelchair users to gain access to the vehicle, sometimes as a passenger but also as a driver. This feature is now a standard for at least some models in the overall range for most major automobile manufacturers. The Hungarian company Kenguru makes an electric vehicle specifically designed for wheelchair users. The Kenguru car is just large enough to accommodate a wheelchair of reasonable size and has a rear hatchback door to permit the wheelchair user to enter from the rear and then drive the vehicle directly. The vehicle is powered by electricity and environmentally friendly, which makes it more convenient for urban living than a rural setting, but this situation is changing.

Another innovation is the hand control system. This may be installed in the vehicle permanently or kept as a portable feature, enabling a disabled driver to modify any existing vehicle or to share a vehicle with an able-bodied driver. The device may be configured to permit the driver to drive with limited or no use of the feet and use a joystick control to activate not just the steering wheel but also lights, windshield wipers, and other important features. These systems are made possible by the increasing use of computers and electronic components in contemporary automobiles—most vehicles of previous generations would be too difficult or too expensive to modify. Hand controls make it possible for people who are senior citizens, suffering from severe arthritis, or without hand or leg functions to continue driving. However, while it may be possible in due course for self-driving cars to be used to transport people in nearly any condition, there are some conditions or degrees of severity that are unsafe for driving because of the inability to control the vehicle safely or because the condition or the medication being used to treat it compromise the judgment necessary to deal with traffic.

Practical Issues

Driving involves more than the control of the car. It is also necessary to obtain insurance and to ensure that the vehicle is maintained at a level that is safe and that conforms to the laws. It is also necessary to have a valid driver's license and for the disabled this usually requires the assistance of a medical doctor, which may be an additional cost. However, in the developed world, most large commercial or

government facilities make provision for a number of designated parking spaces close to the entrance, and these may be larger than standard size so as to facilitate loading and unloading wheelchairs. In any case, most disabled drivers find that it is usually required to plan ahead carefully when making a journey to a previously unvisited destination and to allow more time for contingencies than would be required for able-bodied drivers.

Disabled drivers' interactions with the police and other officials might also be more complex. Disability rights groups around the world lobby government and relevant agencies to try to obtain better terms and conditions and to amend laws that may be discriminatory and that technology and societal change have rendered redundant. This is part of a broader campaign for equal treatment and access.

Distracted Driving

Deaths caused by automobile accidents have been a major problem since the beginning of automobile transportation. Excessive speeds, intoxicated drivers, impatient drivers, and other causes—including distracted driving—have contributed

to a significant annual automobile accident death toll. Distracted driving is anything that distracts a driver from focusing completely on driving the vehicle. Historically, eating, drinking a beverage, lighting a pipe or cigarette, grooming, talking, arguing, children, pets, reading maps, or romantic exchanges between the driver and the front seat passenger have caused distracted driving.

In more recent decades technological developments have added to the list of distractions, including looking at directional devices; watching TV; manipulating a radio, CD player, or MP3 player; or other causes of inattention. All of the distracting devices and behaviors and more have contributed to automobile accidents. Other distractions include visual distractions that cause the driver to take his or her eyes off of the road and/or manual distractions that occur when the driver takes one or more hands off the steering wheel.

Since the advent of mobile phones, distracted driving caused by attending to a mobile phone or other device has been increasing. Texting, cell phones, in-car phones, and other distractions are cognitive distractions that cause the driver to fail to focus on his/her driving. Any distraction causes the driver to fail to focus on driving, which then endangers the driver, passengers, pedestrians, the vehicle, other vehicles, and property. Cognitive distractions caused by texting or by receiving or making mobile phone calls are the result of massive changes in technology. These changes have not been accompanied by increases in disciplined driver safety practices.

Effects

The Centers for Disease Control and Prevention (CDC) has reported that nine or more people are killed and over 1,060 are injured every day in the United States because of distracted driving. Accidents resulting in damage, injury, and death and caused by distractions from texting or phone usage have been increasing. Over 5,400 people were killed and 448,000 injured in driver-distracted wrecks in 2009, according to the National Highway Traffic Safety Administration (NHTSA) of the U.S. Department of Transportation. These figures represent 16 percent of all fatal crashes and 20 percent of injuries from accidents.

Texting has been rapidly adopted by teenagers in U.S. society, tempting many to text while driving. A study by the American Automobile Association

Distracted driving is responsible for more than nine deaths and 1,060 injuries per day in the United States. In 2009, fully 16 percent of all fatal crashes and 20 percent of all injuries from automobile accidents were attributed to distracted driving. All U.S. states have adopted laws to prohibit certain kinds of cell phone usage or texting.

(AAA) Foundation for Traffic Safety found that teenage drivers are the most distracted of all drivers. A study reports that they are distracted as much as 25 percent of the time by electronic communications devices. As a result, teens are more likely to be involved in a distracted-driver accident while texting than are older groups. The NHTSA estimates that 16 percent of teenagers involved in a fatal accident were distracted by texting. Studies have shown that a third of American drivers have either read or sent a text message or e-mail while driving in the 30 days prior to the time they were surveyed.

Drivers distracted by hand-held devices are four times more likely to be involved in vehicle accidents than drivers who do not use them. Texting and cell phone calling are the principal causes. The reason, of course, is that looking at the hand-held device to text or to call takes the driver's eyes off of the road for an average 4.6 seconds. At speeds over 55 miles per hour, this is like driving blind for the length of a football field (100 yards).

Using a cell phone and driving impairs the cognitive reactions of the driver. A University of Utah study found that the driver impairment was as great

as if the driver were intoxicated with a blood alcohol content of 0.08, which is the common legal limit. The National Safety Council has reported that use of headsets is not safer than handling a cell phone or other device. One reason for the lack of greater safety from using a headset is that talking on the phone while driving reduces the brain's engagement with reading and responding to road conditions by 37 percent. Text messaging is an extremely dangerous driver distraction because it distracts visually, manually, and cognitively.

In 2010 distracted driver crashes killed 3,267 people and injured 416,000. In 2011 there were 3,331 people killed in driver-distracted crashes and 387,000 were injured. Two solutions that are being applied to this highway safety problem are education of Americans about the dangers posed by distracted driving and laws to prohibit their use while driving. The laws are like the laws prohibiting drinking alcoholic beverages and driving.

Laws

The problem of distracted driving due to cell phones and texting has led to the adoption of numerous

laws. The Federal Motor Carrier Safety Administration (FMCSA) has issued regulations prohibiting the use of cell phones and texting for bus and truck drivers engaged in interstate transportation. All of the states have adopted laws to prohibit certain kinds of cell phone usage or texting. Some states have adopted laws that prohibit the use of cell phones—including those that are hands free—for bus drivers, and especially school bus drivers. Others prohibit their use by teenagers, novice drivers, and others, including adults.

In some states novice drivers are forbidden to use a cell phone while driving. Some states prohibit all texting while driving. In some states these are primary enforcement offenses, that is, the driver may be cited for using a cell phone without being charged with any other traffic offense. Many localities have adopted local ordinances to prohibit electronic devices that cause driver distraction. The overall solution for most safety experts lies in a combination of regulatory policies and safety training.

Dredging

Both natural waterways, such as bays and rivers, and man-made waterways, such as canals and harbors, are often too shallow for certain deep-hull vessels to navigate safely. In these instances, it may become necessary to artificially deepen the waterway through a process called dredging. A body of water

is dredged by scraping sediment from the bottom using a variety of methods. Through this process, material is removed from the waterways; this allows ships to safely use the body of water without running the risk of hitting bottom. Dredging is not only conducted for navigational purposes. There are also environmental purposes for dredging, such as the removal of toxic materials or objects from a body of water. Dredging may also be used to replenish sand on some public beaches to combat coastal erosion. Despite its positive uses, its negative environmental impacts are especially concerning. In particular, dredging disrupts the natural ecosystems of both the dredged bodies and the disposal site.

How It Works

The primary economic reason dredging is needed is to maintain maritime industries. Due to a variety of processes including natural erosion, fine particulates in the form of silt gradually wash downstream. Over periods of time, the silt gradually fills bodies of water, causing the bodies to eventually become shallower or even creating small islands in the waterway.

It is widely acknowledged that without precaution, dredging can be greatly environmentally damaging. For this reason, disposal of dredged materials is highly regulated by the U.S. Environmental Protection Agency (EPA). The EPA lays out three key criteria that must be met before dredging material may be disposed of: (1) the party must demonstrate a concrete need for dredging, (2) there must be a comprehensive analysis of all reasonable dredging methods and disposal sites for the dredged material, and (3) testing must be performed to ensure that dredged material to be placed will not harm the environment of the dump site.

While there may be a great variety of equipment and highly specialized techniques, all dredging can be put into one of two categories: hydraulic and mechanical. Neither type is more efficient or safer in every context. Hydraulic dredge systems use pumps and are typically mounted on a barge. Once the dredged material is pulled into the system by the pump, it is moved via a pipeline to either the barge or a nearby disposal area. Mechanical techniques remove dredged materials from the body of water in question by using machinery. This is typically done with a clamshell bucket (also known as a grab dredger), but bucket ladder dredgers are also commonly used. Mechanical techniques may be

preferred when there is risk of airborne emissions from the dredged material, such as when said material is particularly toxic or volatile.

Environmental Impacts

As mentioned, dredging may have either positive or negative environmental impacts. Unfortunately, the net impact of dredging is likely more negative than positive. Environmentally positive dredging may be used to reduce exposure of natural and human contaminants that have been brought into a body of water by vessels using it; this type of dredging is called “environmental dredging.”

In the United States, all dredging is overseen by the EPA and the U.S. Army Corps of Engineers, and both agencies pay more attention to the dredging that poses potential negative impact. The potential negative impacts of dredging are complex and varied; in fact, the complexity of the negative impacts often obscures their very existence. The contents of sediments are of major concern regarding the environmental impact of the potential dredge, as sediments in and around cities and industrial areas are often contaminated with a variety of toxic substances. Considering this likely contamination, disposal of dredged sediments from urban areas often amounts to toxic dumping. Thus, dredged materials cannot be put in oceans or other bodies without a permit from the U.S. Army Corps of Engineers, using the above-mentioned EPA criteria.

The potentially toxic artificial contents of a dredge determine most of the negative environmental impact. The release of toxic chemicals from passive sediments can be made active when introduced to the water column. These passive elements include heavy metals and even materials that have been long outlawed, such as DDT. Once reintroduced to ecosystems via the water column, these toxins can once again be consumed by food animals and thus impact humans.

Apart from the introduction of toxins, additional negative impacts to the ecosystem include short-term disturbances in the quality and condition of the aquatic ecosystem. Regardless of intent or methods of dredging, all dredging activity releases suspended sediments into the aquatic ecosystem, and such releases occur over the entire course of the dredge process: excavation, transport of dredged material, and disposal of dredged material. Introducing materials into the ecosystem has the

Mechanical dredging with a clamshell bucket or grab dredger on the Yarra River in Melbourne, Australia, in 2008. Mechanical dredging may be preferable when handling toxic or volatile materials in sediment that could become airborne.

dual effects of reducing the ability of light to penetrate the water and physically altering water flow. Reduced light penetration can result in interfering with the metabolic processes of plants and behavior of aquatic animals.

Altered water flow interferes with animal life by inhibiting feeding mechanisms and trapping debris in gills, especially in younger fish that are incapable of escaping the dredge area; altered water flow can also have similar effects on plant life. Factors that determine suspension issues include the quality of sediments being dredged, the method of dredging and disposal, the water conditions of all ecosystems encountered, and other existing water quality and characteristics.

As with the toxic hazards of dredging, the suspension-based dangers of dredging can be made significantly less hazardous if proper precautions are taken. Dredging is less dangerous when it is performed in man-made bodies, such as locks or dock basins. Luckily, suspension issues typically are limited to an area of less than 0.62 mile (1 kilometer) surrounding the dredge area and last for less than one week in those areas. Likewise, turbidity problems typically last only for the duration of the dredge.

populated states such as California, Florida, New York, and Texas have the highest number of traffic accidents, statistics in the United States show that the number of accidents is slowly decreasing, possibly due to more effective driver education.

Approximately 196.5 million people living in the United States possess a driver license. The driver license in the United States serves two purposes. First, it certifies that an individual has learned how to operate a motor vehicle safely and that they know how to read road signs and follow state and federal laws that apply to driving. The driver license in the United States also serves as a form of photo identification and proof of residency within a particular city, county, or state. Even if someone is not a frequent driver, the driver license serves as the most common form of government-issued identification for employment purposes, along with a social security number. For this reason, most young adults in the United States strive to acquire their driver license as quickly as possible. People who move from one state to another must apply for a new driver license issued by that state; a license is not issued without passing a written test, a road test, or both. The elderly, as well as people who have not driven for a long time due to medical reasons, must also retake a written test, a road test, or both prior to renewing their license.

History

Prior to the 20th century, European and American roads were designed for horse-drawn or pedestrian traffic, and horse-drawn carriages remained the more practical form of transportation. Little has been recorded about the actual training of horse-drawn coach drivers; carriage drivers and horseback riders often learned how to ride and operate horse-drawn vehicles from their parents, friends, or professional trainers. The rules of driving a horse-drawn vehicle did not vary much from state to state, let alone nation to nation. For the most part, if a city or state required a license for carriage drivers or horseback riders, it was to establish ownership of the carriage, horse, or both, rather than whether the person received state-approved training to ride or drive.

In the 19th century, European and American inventors developed a variety of steam-, electric-, and gasoline-powered vehicles that did not require a horse to pull them. Not many of these automated vehicles existed, and only the very wealthy could afford them. As the wealthy were subject to no

Driver Licensing

The estimated number of automobiles on the road around the world ranges from 650 million to over 1 billion. This means that at least 650 million human beings have the ability to drive. As public transportation does not serve all locations equally, and as not all infrastructures support train, tram, bus, bicycle, or pedestrian traffic, it has become essential for individuals—particularly in the United States—to learn how to drive. As the number of cars on the road increases, the occurrence of traffic accidents also increases. While more heavily

restrictions on how they could ride horses or carriages—especially in Europe—they received little or no training on how to drive these new vehicles. The presence of these noisy automated vehicles, which traveled at unpredictable speeds and frequently broke down, frightened horses and caused accidents. Though a horse had the potential to trample a pedestrian if the driver was distracted or driving too fast, a horse's first instinct is to stop if approached by a smaller creature; the rider or driver, rather than the pedestrian, was more likely to sustain injuries in such an event. With the advent of automated vehicles, driving alongside horse-drawn vehicles and pedestrians, a single distracted human driver had greater potential to injure and kill others on the road.

The concept of a driver license for automobile owners began in Germany. The Grand Ducal authorities of Mannheim, Germany, issued a license to the inventor of the modern automobile, Karl Benz, in 1888. Citizens of Mannheim complained about the noise and smell of his *Motorwagen*, so Benz requested and received written permission to drive the vehicle on public roads. This type of license, however, did not establish Benz's driving aptitude.

In 1903, Prussia became the first state in Germany to require mandatory licensing and testing for automobile drivers. A driver could not receive a license to drive a motor vehicle in Prussia without taking a driving test to confirm the ability to operate the vehicle in a safe, responsible manner. In 1910, the German imperial government mandated driver licenses on a national scale, establishing the first national driver education program and a series of tests that would serve as a model for other nations.

In the United States, there is some debate as to which city or state was the first to mandate driver license testing. In 1899, a New York City ordinance stated that a driver of a steam-powered car must be a licensed engineer. In 1903, Massachusetts and Missouri issued the first state driver licenses but required no test of the driver's aptitude.

As ownership of automobiles increased after the introduction of the inexpensive Model T Ford, the number of injuries and deaths caused by motor vehicles in the United States increased dramatically. In 1907, the *New York Times* published an article titled "Better Auto Laws Are Now Needed" in which automobile experts voiced their concerns about the accidents caused by careless, untrained drivers.

Legislators reviewed French and German laws as models but could not mandate a national driver education program due to constitutional rights granted to each state to develop their own education system. In 1908, Rhode Island became the first state to issue driver licenses based on the results of a driving skills test. In 1913, New Jersey became the first state to require that all drivers pass a mandatory examination before receiving a license. This state-mandated exam included a road test and a written test.

By the 1930s, nearly three-quarters of households in the United States owned a car. At the same time, while high schools began to develop driver education programs, many states still did not require a test of driving skills prior to issuing a license to drive. It was customary for the state to charge new drivers 25 to 50 cents in exchange for a driver license. The last state to require drivers to pass a driving exam was South Dakota in 1959. While there are some small variations in traffic laws from state to state, they do not prevent any trained, licensed American from driving across the country. Americans who wish to drive in other countries must obtain an international drivers license, but this may be insufficient preparation to drive in countries with unfamiliar traffic conditions.

Components of Driver Licensing

In the United States, each state has a department of motor vehicles that issues driver licenses and arranges written and practical driving tests. Minors in each state can apply for learner's permits that allow them to drive with a licensed driver in the car, for limited hours and distance each day. In some states there are minimum age requirements for obtaining learner's permits, taking driver education training, and qualifying for official driver licenses. Many states require the successful completion of a driver education course before a young driver can get behind the wheel of a car. Minors in rural states who have experience operating farm equipment, such as tractors or harvesters, often have an advantage over others, as one can acquire permission to drive farm machinery as young as 12 years of age.

In many states, the department of motor vehicles provides an information booklet to new drivers about traffic laws, road signs, the significance of straight and dotted lines on the roads, driving under different weather conditions, speed limits, and laws about driving under the influence. New

drivers must memorize all of the information in the state-issued booklet in order to pass the written test, which in most states is now administered by computer. New drivers must schedule an appointment with the department of motor vehicles to take their written driving test; the test is proctored and graded on site, so that people can get their results that day. It is necessary to pass the written test in order to receive a temporary license or a learner's permit. Some people take online courses to prepare for the written test.

First-time drivers are also required to pass a practical driving test. While the departments of motor vehicles in each state proctor the actual driving tests, they do not provide cars, nor in most cases do they provide driver education. New drivers must find someone who will sit behind the wheel with them and teach them how to drive. While some people learn how to drive a car from their parents, siblings, or friends, others have the opportunity to take driver education classes through their high school. Others take driving lessons from a driver education school. These formal lessons take place in a special car fitted with dual controls, with pedals on the passenger side for the instructor in case the student drives too fast or slow. In the United States, most instruction on learning how to drive automobiles takes place in cars with an automatic transmission, though students can request instruction on a stick-shift car if they wish. Students learn skills such as acceleration and braking; how to watch and anticipate the actions of other drivers on the road; how to make turns; how to get on and off freeway ramps, change lanes, and parallel park; and how to drive in city, residential, and rural traffic. Students may take as many lessons with the instructor as necessary until the instructor and student feel prepared enough to schedule the road test at the department of motor vehicles.

If students fail either the written or practical test, they have the opportunity to retake either exam as often as they wish. As the department of motor vehicles charges a fee for each exam, however, there is motivation to master skills prior to taking the exam.

Impact of Driver Licensing

Teenage drivers are most at risk for getting into accidents due to inexperience and impulsivity. According to various reports, driver license training leads to early licensing, but there is little or no evidence that it reduces the increased crash risk for

beginning drivers. At the same time, statistics show that the number of car accidents, particularly those caused by alcohol abuse or other distractions, have decreased for all age groups. Driver license training plays a major role in educating beginning drivers about seat belt usage, drunk driving laws, and state laws that may ban cell phone use while driving.

Senior citizens, because of failing eyesight, weakened reflexes, and mental deterioration, are also at increased risk for getting into car accidents. For this reason, many states have implemented mandatory driver license retesting on one's 65th birthday. Part of the driver license application and renewal process for drivers of all ages is an eye exam. If a person must wear corrective lenses in order to read the chart for the eye exam, most states will indicate on the person's driver license that corrective lenses are required for driving. If a senior citizen fails the eye exam, even with corrective lenses, it is not likely that his/her license will be renewed.

It is against the law to drive any motor vehicle, whether owned or rented, without a license in the United States. Each state determines its own penalty for driving without a license, depending on the reason for police intervention. For illegal immigrants driving without a license, the penalties can include deportation. Most state departments of motor vehicles do not ask for a birth certificate when one fills out a driver license application, participates in driver license training, or takes a road test. In culturally diverse areas of the United States, driver education and department of motor vehicle forms are available in the major languages spoken in those areas. Providing driver education, forms, and tests in the languages of various immigrant groups retrains those from other countries who drove under different laws, drove under no laws, or had never driven before. Mandatory written and road tests to acquire a driver license ensure that all people within a country understand road signs, comply with speed limits, communicate effectively with other drivers on the road, and avoid distractions while driving in order to avoid accidents.

Driver Licensing, Commercial

Commercial drivers are usually truck or bus drivers. They engage in hauling cargo or passengers over short to very long distances. In the United States, Canada, and other countries, the driving of commercial vehicles requires a special commercial driver's license (CDL).

Early versions of a driver's license were developed in Chicago and New York City. Chicago required all drivers of a motorized vehicle to pass an exam before driving. New York City adopted an ordinance that required steam-powered cars to be driven by a licensed engineer. In 1903 Massachusetts and Missouri issued driver's licenses, but no examination requirements were necessary. For practical purposes, the earliest licenses were identification cards. Many states in the 1930s and 1940s required only the payment of a small fee to get a driver's license. In some cases these could be acquired by mail.

Widespread adoption of driver's license laws to operate a car, truck, bus, or other vehicle began in the 1920s as the number of drivers increased at an enormous rate. With the increases in cars and drivers on the roads, motor vehicle accidents also increased. Many accidents were the fault of inexperienced or careless drivers who were driving more powerful vehicles. At higher speeds, inexperienced drivers or foolhardy drivers were increasingly a danger to themselves and to others as they drove at high speeds or recklessly. To slow or prevent the

rising increase in wrecks that damaged property and killed or injured people, acquiring permission to drive on the public roads was mandated.

As safety concerns increased, public pressure developed to mandate that drivers demonstrate driving competency. Rhode Island instituted the first program for testing drivers before issuing them a driver's license in 1908. By 1913 New Jersey was requiring drivers to pass an examination of driving abilities and also knowledge of highway laws and safety. Other states slowly followed suit.

Prior to 1986 a license to drive a bus or a large tractor-trailer truck or some type of longer combination vehicles (LCVs) varied from state to state. In the District of Columbia and in many states all that was necessary for a commercial driver was a license to drive an automobile. Many states did not have a classified licensing system, nor did they have a system for skills testing the driver applicant on the type of vehicle (personal or commercial) that would be like the one they would be driving.

During the era prior to 1986 many truck drivers were not trained to drive the "big rigs" being introduced to haul larger loads on the Interstate Highway System. As a consequence of their insufficient training, many drivers had avoidable accidents, resulting in property losses, injuries, and vehicular deaths. To deal with the highway damage and slaughter, Congress passed the Commercial Motor Vehicle Safety Act of 1986, which was signed into law by President Ronald Reagan on October 7, 1986. The law requires all drivers of vehicles that have a gross vehicle weight rating (GVWR) of 26,000 pounds (11,793 kg), haul hazardous materials, or carry more than 16 passengers to have a commercial driver's license (CDL). The law also requires tow truck operators to be licensed.

The main purpose of the act was to ensure that those driving trucks, buses, tractor-trailers, or other vehicles that qualify as commercial motor vehicles (CMVs) are qualified and responsible drivers. The act engages in cooperative federalism. The states test drivers and issue licenses, but the minimum standards are set by the Department of Transportation. Only if an applicant for a CDL has been tested by the state in an approved testing facility is a state able to issue a CDL. The examination includes both a written exam and a practical test.

Since April 1992 all drivers of a CMV have had to have a CDL or be in violation of the federal law. The

testing standards have been developed by the Federal Highway Administration (FHWA) and apply to all drivers of Class A trucks (GVWR of 26,001 pounds or more), Class B trucks (GVWR of 26,001 or more) that tow a vehicle not in excess of 10,000 pounds, and Class C trucks that haul hazardous material or carry more than 16 passengers.

While the federal Commercial Motor Vehicle Safety Act of 1986 sets minimum standards for a CDL, states may add more requirements they deem necessary for public safety. For example, in New Jersey a bus, van, or limousine driver must have a CDL in order to legally drive 8 to 15 passengers, which is less than the 16 passengers mandated by federal regulations. In New York a CDL is required to drive a school bus or other passenger transport vehicles listed in Article 19-A of the New York Vehicle and Traffic Law.

The Department of Transportation has set 21 as the minimum age for drivers with a CDL to operate a commercial motor vehicle in interstate commerce. However, some states allow drivers between the ages of 18 and 20 to get a CDL. Their CDL allows them to drive only within their state until they reach the age of 21, when the CDL automatically converts into a federally sanctioned license for interstate driving.

Since 2013, obtaining the CDL has become a strenuous process, with both a written test and a three-part skill exam. The increasing requirements mean that drivers need a proper education in order to pass the CDL exams. For example, the Alabama CDL rule book is 159 pages in length. The division of motor vehicles (DMV) in each state has its own unique set of application procedures and training program regulations. Some states provide training, whereas other states depend upon third parties to provide the training for the CDL exam, all of which may cost the prospective licensee significant fees.

In addition to the road and vehicle operations examinations, a CDL applicant must also pass a medical examination. The medical form must be completed by a physician licensed in the United States. In addition, a doctor of osteopathy (D.O.), licensed physician assistant (P.A.), advanced practice registered nurse, or chiropractor who is clinically competent to perform the medical examination can conduct the medical examination and complete the applicant's medical form. The medical

form must be submitted to the applicant's DMV along with his/her original application. The medical form may not be more than two years old from the date of application. In some states school bus drivers aged 65 and older must submit a new medical form annually. Federal regulations mandate alcohol and drug testing for CDL drivers. All states have regulations for handling those found engaged in driving under the influence of alcohol or engaged in substance abuse.

Driver Licensing Rates

Changes in the number of drivers impact the demand on transportation infrastructure, congestion, pollution, and transportation system and energy demand. While the majority of adults in the United States are licensed drivers, differences in rates of licensure exist between people of different ages, race/ethnicity, and immigrant status, primarily as a result of household income and other socioeconomic differences.

Driver licensing in the United States has not always been as pervasive as it is today. In 1950,

less than half of the population was licensed to drive, but as automobiles became less expensive to own and operate, public policies developed urban infrastructure conducive to vehicular transportation, and as women became more heavily involved in the labor force, licensure rates increased substantially and the growth in the number of drivers in percentage terms exceeded the growth in the total population overall up until the first decade of the 21st century.

In 2010, there were 679.6 licensed drivers per 1,000 people (up from 407.9 in 1950). Because of differentials in licensure rates among race/ethnic groups, continued population growth will increase the number of drivers, but the rate of growth may continue at a slower pace as the United States becomes more racially/ethnically diverse.

Differences by Gender and Age

According to the 2009 National Household Transportation Survey, 88 percent of the adult population was licensed to drive. Historically, women were less likely to drive than men, but as women became more involved in the labor force, the gap in licensure between men and women closed so that by 2009, 90 percent of all men and 85 percent of all women were licensed to drive and over 90 percent of both men and women between the ages of 35 and 60 were licensed to drive. Only in the oldest age groups do gaps in licensure rates of over 10 percent remain—primarily as a result of changes in women's roles and generational attitudes.

The next several years will see a change in the characteristics of elderly drivers as the baby boom generation (those born between 1945 and 1964) reach retirement age. In 2009, 64 percent of non-drivers were younger than age 25 or aged 65 years and older. While overall 60.9 percent of nondrivers were women, 76 percent of nondrivers aged 65 years and older were women.

Differences by Race/Ethnicity

At 91.3 percent, non-Hispanic whites have the highest driver licensure rates compared to other racial/ethnic groups, and non-Hispanic blacks and Hispanics have the lowest licensure rates at 77.9 and 77.6 percent, respectively. All other groups have rates closer to non-Hispanic whites (at 86 percent). The lower licensure rates for non-Hispanic blacks and Hispanics are primarily a result of lower

incomes as well as having a large proportion of the population living in central cities where other forms of transportation are available or a result of having a significant proportion of immigrants (for Hispanics). Although lower relative to non-Hispanic whites, the differences in licensure between men and women for non-Hispanic blacks are less than 4 percent overall.

Among the two groups with relatively large immigrant populations, non-Hispanic Asians and Pacific Islanders and Hispanics have larger gaps in licensure between men and women (7.3 and 15.1 percent, respectively). In fact, licensure rates among Hispanic males are similar to those of non-Hispanic whites (at 86 percent overall and over 90 percent for all age groups from ages 30 to 64). Since these are two of the fastest growing groups in the United States, increases in licensure for Hispanic and Asian women will have a significant impact on growth in the number of drivers in the United States in the future.

Immigrant Status

The longer immigrants live in the United States, the more likely they are to become drivers. This change in status can be understood as one indicator of assimilation to the dominant culture. Still, rates of licensure are lower for immigrants who have lived in the United States for a long period of time. Overall, 81.5 percent of those born outside the United States were licensed to drive in 2009 (compared to 89.9 percent of the population born in the United States). Women immigrants have the lowest licensure rates. In fact, at 90.1 percent, male immigrants have licensure rates equal to that of the U.S. born (91.5 percent). Only 73.6 percent of foreign-born women were licensed to drive in 2009, compared to 88.3 of U.S.-born women.

Income Differences

The percentage of people licensed to drive increases with income. There is a symbiotic relationship between income and driving. An individual with a license to drive and access to an automobile is able to access a wider variety of jobs within a larger expanse of geography without dependence upon fixed travel schedules of public transportation. At the same time, higher income enables one to acquire, operate, and maintain a vehicle. In 2009, 94.8 percent of individuals with household incomes of \$75,000 or greater were licensed to drive, whereas only 72

percent of people with household incomes less than \$25,000 were licensed to drive. In addition, 95.8 percent of employed people were licensed to drive, compared to 76.3 percent of people unemployed or not in the workforce.

Encyclopedia of
TRANSPORTATION

Economic Development

Transportation serves an important function in transforming human society and impacting economic development. This has been studied in several fields, including sociology, geography, planning, economics, and engineering. The diversity of fields has resulted in a complex mixture of theories and empirical studies.

This article addresses the role of transportation in economic development from four perspectives. First, the broad impacts of transportation on economic development are briefly summarized. Second, the impacts are explained by regional economic theories. Third, airports are used as an example for discussing the role of transportation in economic development. Fourth, the complexity of transportation impacts on economic development and the possible reasons for this are explored.

Transportation Impacts

Transportation modes for general public use include bicycles, animals such as horses and donkeys, boats and ferries, personal vehicles, public transportation (such as buses, subways, intercity rail transit, and high-speed trains), airplanes, and others. These transportation tools would not have been used widely without the companion of transportation infrastructure including roads, waterways, highways, railroads, airports, and others.

The advances in transportation tools and improvements in transportation infrastructure have played an important role in decentralizing population and businesses as well as promoting economic growth and development.

The past century saw urban decentralization and low-density sprawl largely due to transportation and communication improvements. Convenient highway networks and personal vehicles allow people to live farther from their workplaces while enjoying low living costs and high quality of life in suburban and rural areas adjacent to metropolitan areas. In addition, the greater availability of air transport reduces travel time between cities, enables increased interactions between them, and integrates otherwise isolated economic regions into a nationwide or worldwide economic region. Intercity rail transit and high-speed trains, which provide safer trip experiences, could further promote the decentralization of population and firms.

Regional Economic Explanations

The way transportation affects economic development has been explained by many theories. Here three regional economic theories are discussed: central place theory, growth pole theory, and neo-classical growth theory.

According to central place theory, transportation infrastructure enables the flow of raw materials, capital, finished goods, consumers, and ideas

between central locations and their hinterlands. Transportation costs are vital for determining locations for both firms and households. For the sake of maximizing profits, business locations are typically chosen based on where costs (including transportation costs) can be minimized and demand is maximized. Meanwhile, preferred locations for households have low land costs and offer easy access to both high wage employment and urban amenities in central areas and natural amenities in outlying areas.

In growth pole theory, the notions of spread and backwash serve to assess how mutually dependent metropolitan areas and their surrounding rural areas are on each other in terms of economic growth and development. This theory mostly looks at highways as a catalyst of change. However, a highway connecting a metropolitan area with its surrounding areas alone represents neither a necessary nor a sufficient influence for economic growth in the two areas; the alternative and equally possible outcome would be economic decline.

According to neoclassical growth theory, transportation infrastructure contributes to the production function. The production function assumes a relationship between inputs and outputs into the production process in an area. Accordingly, investing in transportation infrastructure serves as a type of public capital and flows into the production process. A large proportion of studies in neoclassical growth theory investigate how public capital and economic productivity are connected through the production function. Most claim that economic output increases with an augmentation of transportation infrastructure.

Airports as an Example
